Postoperative radiotherapy in DBCG during 30 years. Techniques, indications and clinical radiobiological experience

MARIE OVERGAARD & JENS JUUL CHRISTENSEN

Department of Oncology and Department of Medical Physics, Aarhus University Hospital, Aarhus, Denmark

Abstract

During the time period 1977–2007 postoperative radiotherapy in DBCG has varied considerably with regard to techniques and indications together with changes in the extent of surgery and adjuvant systemic therapy. The radiation treatment has been developed on the basis of clinical, radiophysical and radiobiological principles, encompassing also practical problems such as available equipment in the different centres and at times lack of sufficient machine capacity.

The paper focus especially on the comprehensive work done prior to the DBCG 82 b&c studies, in order to optimize radiotherapy in all aspects prior to the evaluation of the efficacy of this treatment modality. The results from these trials did succeed in clear evidence that radiotherapy has an important role in the multidisciplinary treatment of early breast cancer. In parallel to these studies a new and challenging use of radiotherapy after breast conserving surgery was evaluated in the DBCG TM 82 protocol. The experience obtained with different techniques in this study formed the basis for the current principles of radiotherapy after lumpectomy.

Reduction of radiation related morbidity has been a major issue for the DBCG radiotherapy group, and in this aspect several studies, including quality control visits, have been carried out to make the relevant modifications and to evaluate deviations from the guidelines between the centres. The background for the changes in radiotherapy is described for each of the programme periods as well as future perspectives which will include further refinements of the target and adjustments of dose and fractionation in selected patients.

In the beginning of the 1970's the standard treatment for early breast cancer in Denmark was simple mastectomy followed by loco-regional radiotherapy according to the results from the Copenhagen study comparing simple mastectomy plus radiotherapy versus radical mastectomy alone and similar studies [1-4]. No adjuvant systemic therapy was recommended. Most patients were treated with orthovoltage equipment with the McWhirter technique where the dose aim was 40-45 Gy in 18-20 fractions over 3 weeks. However, during this time period more and more megavoltage equipment was installed in the larger radiotherapy departments and therefore treatment techniques for postoperative radiotherapy in early breast cancer with megavoltage irradiation were developed. Typically the treatment technique included an anterior field against the lymph nodes in the periclavicular and axillary region in combination with tangential opposed fields to the chest wall. The position of the fields were planned and verified on a simulator by the use of bone structures as landmarks. The dose aim was 54 Gy in 24 fractions maximum dose in the anterior photon field whereas the dose for the tangential fields was calculated at the central axis between the two fields corresponding to the later ICRU-reference point. Dose homogeneity was aimed for by the use of standard wedges. The extension of the photon fields was individualized according to the location of the primary tumour and the loco-regional spread. At that time the target definitions which nowadays form the basis of dose planning were just under development and the first ICRU report including target definitions was published in 1978 (ICRU 29) [5].

Parallel to the development in radiotherapy with more effective high-energy equipment and new treatment techniques the first convincing results of adjuvant systemic therapy in early breast cancer [6,7] appeared in the mid seventies. Especially premenopausal women with node positive disease

seemed to obtain a pronounced improvement in disease-free survival. These results led to a paradigm shift in the treatment of early breast cancer towards a more multidisciplinary approach, and it was within this time period that the DBCG group was formed, and encouraged also to evaluate adjuvant systemic therapy together with optimal loco-regional therapy in high-risk patients [8,9].

In the following the important and major changes in the radiotherapy recommendations during 30 years in DBCG are described in relation to the different programmes.

Radiotherapy in DBCG 77

One of the major aims of the DBCG organization [8] was to develop national treatment strategies to assure a uniform treatment throughout the country and to allow conduction of national clinical trials. With the introduction of the DBCG-77 protocols it was decided that total mastectomy and axillary sampling should be offered to all patients with early breast cancer. By this pathologic staging the patients could be divided into a low-risk group (node negative and T \leq 5 cm) or a high-risk group (node positive and/or invasion to the pectoral fascia and/or T3 or T4 tumours). Patients belonging to the lowrisk group were not recommended further treatment neither postoperative radiotherapy nor adjuvant systemic therapy. High-risk patients were treated with postoperative loco-regional radiotherapy as a standard or included in DBCG protocol-77b or DBCG-77c [10–12]. In the 77b study the value of different adjuvant systemic chemotherapy or immunotherapy was studied in addition to postoperative radiotherapy. In the protocol DBCG 77c endocrine therapy or immunotherapy in addition to postoperative radiotherapy was evaluated in all postmenopausal women without any upper age limit. The protocols included recommendations for the postoperative radiotherapy (Table I). Due to the protocol design which described simultaneous chemotherapy, it was decided to modify the total dose aim to avoid serious acute skin reaction due to interaction with radiation (Table III). Publications and clinical experience had shown enhanced normal tissue reactions (acute and late) in patients who received simultaneous chemotherapy and radiotherapy [13]. For practical reasons it was decided to keep the same dose aim in all treatment groups irrespective of type of systemic therapy or none. As mentioned above the description of target definitions and target depth doses was about to be described in the ICRU 29 Report. This was known by the oncologists and physicists in the DBCG group and included as a recommendation for the dose calculation. Priority was made to obtain the same minimum dose at depth in the axilla to assure optimal tumour control in all patients irrespective of thickness of the patient. The reference point for the dose calculation in the axilla was chosen to be the midaxilla (MA) corresponding to the half of the anterior-posterior (a-p) diameter in cm at the bottom of caput humeri (Figure 1). This magic reference point showed to be relevant also for the definition of the axillary target depth in later DBCG programmes.

To reach the minimum dose according to increasing depths of the midaxilla in different patients it was necessary to increase maximum doses as shown in Figure 2. However, the upper limit was set to be 54 Gy. There were two treatment techniques available. A new three-field technique was introduced using an anterior photon field against the periclaviculary and axillary node areas combined with one anterior electron field covering the remaining part of the chest wall (Figure 3). It was not intended to include the internal mammary nodes. The other available technique was an anterior photon field to the periclavicular and axillary regions combined with two tangential opposed photon fields to the chest wall.

Due to the fact that there was no access to megavoltage treatment for patients living in peripheral parts of the country it was allowed to offer these patients orthovoltage treatment ad modem McWhirter [14]. Moreover, even in the larger departments the machine capacity was not large enough to accumulate all patients referred for radiotherapy. Therefore, in four of the centres it was decided to use hypofractionation with 2 weekly fractionations allowing the double number of patients to be treated. The fifth megavoltage centre continued to give conventional 5 fractions per week. The two fractionation schedules were thus a minimum dose of 36.6 Gy in 12 fractions with 2 fractions per week or 40.92 Gy in 22 fractions with 5 fractions per week, corresponding to a CRE value of 1335 reu. The Ellis NSD formalism and the CRE- derivative by Kirk et al were used to calculate isoeffects between these two regimens Figure 4 [15, 16].

The loco-regional radiotherapy in the DBCG 77 protocols resulted in satisfactory loco-regional tumour control especially in patients, who were also treated with systemic therapy [12]. However, in the departments using the hypofractionation schedules it became obvious after two years that the radiation morbidity had increased remarkably

Year	Patient age and indication	Targets	Dose/fx/time	Techniques	Remarks
1977	All high-risk, all ages	Chest wall, axilla, periclavicular area	41 Gy/22 fx/5 ¹ / ₂ wk or 36 Gy/12 fx/6 wk or 36 Gy/20 fx/4 wk (orthovoltage)	3 field tangential or 2 field electron/ photons 4 field orthovoltage	Simulator plan for MV treated pts. Mandatory central registration of treatment
1982	High-risk (<70 years) randomized to RT in 82b&c protocols. Standard to all non-protocol pts.	Chest wall, axilla, periclavicular area, parasternal	50 Gy/25 fx/5 wk or 48 Gy/24 fx/5 wk or 36 Gy/20 fx/4 wk (orthovoltage)	3 field anteriorelectron/photon.3 field widetangential4 field orthovoltage	Simulator plan for MV treated pts. Mandatory central registration of treatment
1989	High-risk (\leq 45 years) with 4+ pos. nodes All pts with invasion of pectoral fascie.	Chest wall, axilla, periclavicular area, parasternal. Chest wall only to pts with pectoral fascie invasion.	48 Gy/24 fx/4 ¹ / ₂ wk	3 field anterior electron/photon. or 3 field wide tangential.	Simulator plan for all pts. Central registration of treatment -not mandatory.
1995	All premenopausal high-risk pts. All pts with invasion of pectoral fascie	Chest wall, axilla, periclavicular area, parasternal. Only level 3 in axilla if ≥ 10 nodes removed.	48 Gy/24 fx/4 ¹ / ₂ wk	 3-4 field anterior electron/photon. or 3 field wide tangential. 	Simulator plan for all pts. Central registration of treatment-not mandatory. First quality round and report (1996).
1999	All high-risk pts <70 years. Not standard to pts. ≥70 years. All pts with invasion of pectoral fascie	Chest wall, axilla, periclavicular area, parasternal. Only level 3 in axilla if \geq 10 nodes removed.	48 Gy/24 fx/4 ¹ / ₂ wk	3-4 field anterior electron/photon.3 field wide tangential.	Simulator plan for all pts. Central registration of treatment – mandatory from 2000. Flensborg joined DBCG 2000. Second quality round and report (2000).
2003–2007	All high-risk pts exclusive pts with micrometasis only Not standard to pts >70 years All pts with invasion of pectoral fascie	Chest wall, axilla, periclavicular area, parasternal (only to pts with tumors at the right side). Only level 3 in axilla if ≥ 10 nodes removed.	48 Gy/24 fx/4½ wk	 3–4 field anterior electron/photon. or 3 field wide tangential. 	Development of CT planning 2002. Central registration of treatment mandatory.

Table I. DBCG Recommendations for postmastectomy radiotherapy 1977-2007.

compared to previous experience. Impairment of shoulder movements, lymph oedema, severe fibrosis in the irradiated areas, spontaneous rib fractures and lung fibrosis occurred much more frequent than expected [17,18]. Therefore in one of the centres, Aarhus, it was decided before the end of the protocol period to stop the use of hypofractionation and switch to conventional fractionation. This later allowed comparison between the early and late normal tissue effects in patients treated with these two schedules with and without adjuvant systemic therapy [17–30], Furthermore has the detailed morbidity recording in these patients together with access to genetic material and fibroblast cell cultures from the patients given us the basis for research and identification of genetic profiles for risk of radiation induced morbidity [31–42].

Radiotherapy in DBCG 82

In contrary to the increased radiation morbidity in the DBCG 77 programmes the preliminary results of the effect of adjuvant systemic therapy appeared in the beginning of the 80's showing significant

Figure 1. The x-ray used for the target determination showing the reference point for the MA measurements. The levels of the CT-slices are indicated at the margin. The position of the patient is not standard because of the small scan diameter of the CT-scanner.

improvement in disease-free survival [10–12]. These results supported the Fisher theory [43] which says that breast cancer is mainly a systemic disease and therefore only improvements can be obtained with more effective systemic therapy whereas more aggressive loco-regional therapy with more extensive surgery and/or radiotherapy was not likely to improve overall results as stated in the Halsted theory [44]. Thus, in the light of the recent bad experience with unacceptable radiation morbidity together with the general opinion which held to the theory, that postoperative radiotherapy would not improve overall survival, it was decided to design a trial to evaluate whether postoperative radiotherapy is necessary in high-risk breast cancer patients who also receive adjuvant systemic therapy. The 82b and c protocols were designed as two three-arm studies comparing postoperative radiotherapy after mastectomy and systemic therapy versus the same systemic therapy alone versus the same systemic therapy plus additional systemic therapy in high-risk patients [10–12].

Due to the experience with increased radiation morbidity in the previous protocol, the guidelines for radiotherapy in the DBCG 82 protocols were comprehensively prepared to optimize the radiation treatment in all respects. It was decided to follow the ICRU target definitions. To obtain consensus about the exact target volume to include, the members of the radiotherapy committee were asked to draw target volumes on a number of CT slices of a patient in treatment position as shown in Figures 5 and 6. Further, it was decided that the target volume should include all loco-regional node areas (periclavicular, axillary, and internal mammary nodes (IMN)) as well as the chest wall with sufficient margin around the surgical scar. After consensus about the target definitions it was possible to make field arrangements on a simulator to cover these areas as seen in Figure 3. An anterior photon field

Figure 2. Left: The upper curve shows the common peak dose of 54.0 Gy in 24 fractions for all patients and the lower curve indicate the dose to the later defined the midaxilla (MA) target depth.

Middle: The lower curve is the prescribed minimum dose to the target and the upper curve is the corresponding peak dose. For big a-p diameters the minimum dose drops down due to the upper dose limit of 54.0 Gy for the peak dose. Right: The median dose concept results in symmetrical peak and minimum doses. The demand for a dose deviation less than +10% cause a energy shift for big a-p diameters.

could cover the deep part of the target in the axilla and the periclaviculary area, whereas the more superficial part of the target on the chest wall and IMN area could be covered by anterior electron fields. Following this procedure in one patient, a number of patients of different sizes were scanned to test the variation of the target between patients. On the basis of these information the DBCG 82b&c irradiation techniques was developed and described and thus it was possible to make field arrangements in every patient using only a simulator. In Figure 7 it is demonstrated how the anterior photon field was angled to improve the junction between the photon

Figure 5. Some of the proposals for the target. The green line indicates the DBCG target. The slice shows the situation at the midaxilla (MA) reference point.

Figure 6. The depth of DBCG target defined from CT slices with 2 cm interval. The depth of the dashed curves is equal to the corresponding colored curves plus 0.5 cm.

and electron field. The choice of electron energy for the IMN field and the chest wall was based on ultrasound measurements of the distance between skin surface and pleural surface at relevant points in both fields. Although most patients were treated with the anterior three-field technique using a combination of photon and electron fields the, guidelines also included recommendations for a three-field photon technique using wide tangents to include the chest wall and internal mammary nodes combined with an anterior periclavicular field (Figure 3).

To avoid interaction with chemotherapy it was chosen to give sequential radiotherapy and chemotherapy with a one to two weeks interval between start and end of radiotherapy and chemotherapy (Tables I and III). Further standard fractionation schedules were chosen, either 50 Gy in 25 fractions over 5 weeks or 48 Gy in 22 fractions in 4 fractions per week [12,45]. In addition, it was planned to record all individual measurements and doses as well as a prospective registration of acute and late radiation morbidity [45,46].

The requirements about minimum dose at the deep part of the target in the axilla were replaced by the use of median dose to the target, which includes a dose variation between +/-10% for the photon fields as seen in the right panel in Figure 2. The calculation of the dose to the individual fields was based on standard tables and therefore dose contributions from transmission or scatter from the other fields were not included (Figure 8). At a later

Figure 7. A scan in the thorax region with indication of the lung and the DBCG target. The tree colored lines point out the borderlines between the photon and electron field. The magenta line marks a vertical beam at the inside of the thorax wall. The blue line is situated 1 cm inside the lung. The red line shows the situation with the gantry turned 10-15 degrees from vertical position and the borderline 1 cm inside the lung defined by an x-ray.

At the right side of the figure the depth of the DBCG target is indicated by the green lines for a number of slices. The tree colored lines marks the borderlines between the photon and electron field. The black dot at the surface shows the separation of the parasternal and the scar region.

revision of the dose in the 89 programme, the knowledge of these dose contributions resulted in a reduction of the dose to 48 Gy in 24 fractions to compensate for the more intensified chemotherapy.

A comprehensive audit of the radiotherapy used in the 82b and c protocols as well as the outcome with respect to loco-regional and distant tumour control has been described in details elsewhere [45-47]. Overall, the addition of post-mastectomy radiotherapy in high risk pre- and post-menopausal patients in spite of adjuvant systemic therapy has demonstrated a substantial benefit in terms of loco-regional tumour control and improved long-term survival [48-52]. Thus, these results have clearly demonstrated the proof of principle that primary locoregional tumour control has impact on survival even in patients who also receive an adjuvant systemic therapy [53]. Ongoing studies based on material from the tumour biobank in the DBCG 82b and c protocols are underway to identify genetic and molecular targets which in details may identify the patients who especially may benefit from postmastectomy irradiation [54-57].

With regard to radiation morbidity, this has been evaluated in details by examination of all patients in one centre. The main conclusion is that the late morbidity caused by irradiation was mild and only moderately increased compared to non-irradiated patients. Further, the registry based study of all patients with respect to cardiac morbidity and mortality did not demonstrate radiation related cardiac morbidity within 12 years of observation [58,59]. Neither have preliminary results of 25 years' follow-up of the DBCG 82b and c protocols indicated increased cardiac mortality in irradiated patients.

Radiotherapy in DBCG 82 TM

Parallel to evaluation of post-mastectomy irradiation in the DBCG 82b and c protocols, the concept of breast conserving therapy was planned [60,61] and evaluated in the TM 82 protocol [62-65]. The majority of the patients included in this protocol were low risk (node negative and tumour ≤ 5 cm) and therefore the target in patients randomized to breast conserving therapy was only the residual breast including underlying chest wall, whereas similar patients treated with mastectomy did not receive postoperative radiotherapy. However, highrisk patients included in this protocol irrespective of primary surgery received loco-regional postoperative radiotherapy to target areas analogue to what is described in 82 b and c protocols. The guidelines for radiotherapy after breast conserving surgery and axillary dissection were described separately as given in Table II. Two treatment techniques were described for treating the breast. Most patients were treated with tangential photon fields using supervoltage 6-10 MV photon beams to the breast. But in 3 centres an anterior electron field including all breast tissue was chosen, preferably in patients with small breasts. Wax compensation was used around the breast to even out the distance from the beam

Figure 8. Left: The depth dose curve for the open field is shown in black. To this curve we have to add the dose from electron contamination from the Perspex tray (green) and the transmitted photon dose from the electron fields. Middle: To the standard 10 MeV electron depth dose we must add the contribution from the photon field containing electron contamination

and photon transmission. And on top of that the photon transmission from the electron field adds up.

Right: The same situation as in Figure 6b but the transmitted dose is higher due to the higher electron energy.

entrance to the pleural surface assessed by ultrasound. Electron energies from 6–20 MeV were used, and the prescribed dose was 50 Gy median absorbed dose with the 85% isodose line at the pleural surface [66].

At that time the skin 3 cm around the lumpectomy scar was included in the target and therefore bolus was used during treatment. However, if severe skin reaction occurred, bolus was discontinued during remaining treatment as well as during boost treatment. All patients received a boost of 10 to 24 Gy in 5 to 12 fractions. Most patients were treated with electron boost fields, but photon fields were used in patients with a deep seated tumour bed and interstitial brachytherapy was used in one department where this was technically possible. The cosmetic outcome in relation to the different treatment techniques, has been evaluated in details as described in [66–68].

All patients surviving more than 3 years after initial treatment without recurrence in the group treated with lumpectomy and radiotherapy were called for examination with the purpose of evaluating the cosmetic outcome in relation to different treatment techniques. On the basis of this study [66] the electron technique including whole breast irradiation was found to be inferior to the photon technique and therefore this treatment technique was abandoned from 1993. The evaluation of the cosmetic results in this study also lead to corrections of the surgical technique, especially by avoiding the same incision for axillary dissection and lumpectomy in laterally localized tumours. Finally, the use of bolus on the lumpectomy scar was also found to impair the cosmetic outcome and therefore the use of bolus was later stopped.

In the DBCG 82 TM protocol the intention was only to use conventional fractionation in patients receiving radiotherapy after breast conserving surgery.

Radiotherapy in DBCG 89

The DBCG 89 protocols mainly addressed questions regarding more specific and more intensive systemic therapy on the basis of predictive and prognostic factors, such as oestrogen receptor status and prognosis in relation to malignancy grade. Regarding the loco-regional treatment, only preliminary results from the DBCG 82b and c protocols were available [48]. A very high incidence of locoregional recurrence was found in both pre-and postmenopausal women randomized to systemic therapy alone compared to patients treated with postoperative radiotherapy plus the same systemic therapy. But in a small sub-group, namely patients younger than 45 years with 4 or more positive nodes, a significant decrease in survival was found when treated with systemic therapy alone [12]. However, the interpretation of these early results by the DBCG

Year	Patient age and indication	Targets	Dose/fx/time	Boost	Techniques	Remarks
1977	Not used					
1982	Pts randomized to BCT in TM82 protocol.	Residual breast + regional RT if node pos.	50 Gy/25 fx/5 wk	10–24 Gy/5–12 fx or equivalent interstitial RT	2 field tangential 3 field wide tangential. or one anterior electron field	Simulator plan for all pts. Mandatory central registration of treatment
1989	All pts given BCS	Chest wall, axilla, periclavicular area, IMN. Chest wall only to pts with pectoral fascie invasion.	48 Gy/24 fx/4½ wk	10–16 Gy/5–8 fx	2 field tangential 3 field wide tangential. one anterior electron field (stopped 1992)	Simulator plan for all pts. Central registration of treatment -not mandatory.
1995	All pts given BCS	Chest wall, axilla, periclavicular area, IMN. Only level 3 in axilla if ≥ 10 nodes removed.	48 Gy/24 fx/4½ wk	10–16 Gy/5–8 fx	2 field tangential 3 field wide tangential	Simulator plan for all pts. Central registration of treatment -not mandatory
1999	All pts given BCS	Chest wall, axilla, periclavicular area, IMN. Only level 3 in axilla if ≥ 10 nodes removed.	48 Gy/24 fx/4½ wk	10–16 Gy/5–8 fx	2 field tangential 3 field wide tangential.	Simulator plan for all pts. Central registration of treatment – mandatory from 2000.
2001	All pts given BCS Including pts. with DCIS	Chest wall, axilla, periclavicular area, IMN (only to pts with tumors at the right side). Only level 3 in axilla if ≥ 10 nodes removed.	48 Gy/24 fx/4 $\frac{1}{2}$ wk	10–16 Gy/5–8 fx Not standard in pts >50 yr	2 field tangential 3 field wide tangential.	Development of CT planning. 2002 Central registration of treatment

Table II. DBCG recommendations for radiotherapy after breast conserving surgery (BCS) 1977-2007.

IMN: Internal mammary nodes; RT: Radiotherapy.

Steering Group was, that the high rate of locoregional recurrences could mainly be explained by the insufficient axillary dissection and the rather weak CMF schedule used in the DBCG 82b protocol and therefore might not solely indicate radiotherapy in all high risk patients in the 89 programmes. Along with that the international consensus about postmastectomy radiotherapy in the late 1980's was very negative since results from overview analyses had shown long term negative outcome of postoperative radiotherapy with excess mortality in irradiated patients who survived 10 or more years after primary treatment compared to similar non-irradiated patients [69]. Therefore it was decided by initiation of the DBCG 89 protocols that postmastectomy irradiation was only indicated in patients, who had tumour invasion through the pectoral fascia and in patients younger than 45 years with 4 or more positive nodes. The treatment techniques for postmastectomy irradiation remained unchanged from the 82 period and the combined anterior photon/electron 3-field technique became the preferred technique (Table I). However, in node negative patients who had invasion into the pectoral fascia, the target included only the chest wall.

Since all orthovoltage units closed in the late 1980's, only megavoltage irradiation was allowed from 1989 and onwards (Tables I and II).

Based on the results from the DBCG 82 TM study and similar randomized trials, which all confirmed that breast conserving surgery plus radiotherapy gave similar results to mastectomy, it was decided that breast conserving therapy could be offered as a standard treatment to eligible patients [70]. Postoperative radiotherapy was found indicated in all patients after lumpectomy, but patients younger than 45 years with 4 or more nodes positive should also receive regional lymph node irradiation in addition to irradiation of the residual breast tissue. The two treatment techniques, either tangential photon fields to the breast or an anterior electron field as described above, continued as standard techniques [Table II].

Table III.	Timing	of radiotherapy	(RT) and	chemotherapy	in DBCG.
------------	--------	-----------------	----------	--------------	----------

DBCG programme	Sequence and type of chemotherapy	Remarks
1977	RT concomitant with $12 \times C$ or $12 \times CMF$	4 weeks cycle. C given orally, MF i.v. day 1 and 8.
1982	RT sequential with $8 \times CMF$	4 weeks cycle. CMF i.v. One cycle before start of RT, seven after.
1989	RT concomitant/sequential with $9 \times CMF$ or $9 \times CEF$	3 weeks cycle. CMF/CEF i.v. One cycle before start of RT. Cx2 during RT. CMF/CEF after.
2001	RT after $7 \times CEF$ Subsequent followed by Herceptin (from 2006)	3 weeks cycle. RT given up front/sequential C if non-radical surgery.
2007 1977–2007	RT after $3 \times EC + 3 \times T$, but concomitant with Herceptin Endocrine therapy, mostly Tamoxifen 20-30 mg daily has been given simultaneous with RT in all programmes.	3 weeks cycle.

C: Cyclophosphamide; M: Methrotrexate; F: 5-Fluouracil; E: Epirubicin; T: Taxotere.

The dose to the loco-regional target irrespective of type of surgery was reduced to 48 Gy in 24 fractions with 5 fractions per week due to the timing of concomitant cyclophosphamide and radiotherapy and more intensive chemotherapy with 3 weeks' interval and randomization to CEF vs. CMF in the DBCG 89d protocol [Tables I and III] [9]. Also the boost dose was reduced to 10 Gy in 5 fractions in patients having lumpectomy with a resection margin larger than 5 mm from the invasive tumour and to 16 Gy in 8 fractions in patients with a smaller margin or DCIS close to margin. The boost techniques remained unchanged from the previous protocol but it became mandatory for the surgeons to mark the tumour bed with clips and also to separate the incision for axillary dissection from the incision for lumpectomy in laterally localized tumour with the aim to reduce the boost volume (Table II).

When the results from the follow-up examination of all patients in the DBCG 82 TM protocol became available in 1992, the anterior electron beam technique was abandoned due to inferior cosmetic results with marked late skin reactions such as teleangiectasia and dyspigmentation [66,68]. At the same time the 4 fraction-per-week schedule, which had been used in some departments to be able to do machine checks during normal working hours, was stopped in addition to other minor corrections (Table II).

Due to the very high recurrence rates in the DBCG 82 b and c studies, which in particular occurred in the axilla and on the chest wall, the surgeons did major efforts to improve the surgical technique, especially to improve the axillary dissection [8,9]. Therefore from 1994 the requirements for a proper axillary dissection became the removal of at least 10 nodes compared to 4 nodes previously.

In the beginning of 1995 an analysis of the 82b study showed significant survival benefit in all premenopausal patients who after mastectomy received radiotherapy in addition to CMF. Therefore, the indications for postmastectomy irradiation and regional nodal irradiation after breast conservative surgery were extended to include all pre-menopausal node positive patients. To avoid complications such as lymph oedema and impairment of shoulder movements with a combination of radiation and more aggressive axillary surgery, the target in the axilla was reduced to include only level 3, whereas the periclaviculary and internal mammary nodes were included as previously described (Table I and Figure 3).

During the 1990's the radiotherapy guidelines were revised several times and quality control visits in all 6 Danish megavoltage centres were carried out in 1996. This process did later also include the Department of Radiotherapy, St. Franziskus-Hospital in Flensburg, which from 2000 became the seventh megavolt centre in DBCG. Since then this department has in close collaboration with the DBCG radiotherapy group treated patients from the southern part of Jutland following the DBCG guidelines and reporting the radiotherapy data to the central DBCG registry (Table I).

In 1999 the indications for post-mastectomy radiotherapy were extended to include also all post-menopausal patients due to publication of the results from the DBCG 82c protocol, which showed significant benefit of radiotherapy both in terms of local control and 10-year-survival, similar to the 82b study. Thus, during 1999 the number of patients, who should routinely receive postoperative radiotherapy increased dramatically and this lead to longer and longer waiting times and a need for larger treatment capacity in the country.

Radiotherapy in DBCG 99

In general, the indications for post-operative radiotherapy after mastectomy and lumpectomy have not changed since 1999. There is no upper age limit for standard radiotherapy after lumpectomy, whereas post-mastectomy irradiation in high-risk patients older than 70 years is based on individual evaluation of benefits versus risks in relation to medical conditions.

The timing of radiotherapy and chemotherapy has changed over the years as previously mentioned and described in Table III. However, since 2001 it has been standard to give chemotherapy first, followed immediately by radiotherapy except in patients with residual tumour after surgery. There is no clear evidence neither from the literature nor from previous DBCG studies what the optimal timing is [71–73].

Along with the installation of new equipments with CT dose planning systems and new treatment facilities including multi-leaf collimators it has been necessary to change the guidelines and revise the targets accordingly. Thus, it became clear that inclusion of the internal mammary nodes was not always sufficient with the previous standard techniques [74]. Moreover it became clear that especially the use of wide tangential fields in patients who should receive loco-regional irradiation after lumpectomy, would often include large volumes of ipsilateraly lung, and also the anterior part of the heart, and sometimes also parts of the opposite breast. Thus a serious problem was defined, since there is clear evidence that inclusion of just a smaller volume of the anterior part of the heart will result in excess cardiac morbidity and mortality due to ischemic cardiac disease, which could counterbalance a moderate benefit from radiotherapy. Further, the standard adjuvant chemotherapy in most patients now includes more cardiotoxic drugs, such as anthracyclins and Herceptin. Analysis of a study including different doses of anthracyclins in combination with postoperative radiotherapy, including different volumes of the heart in the target has shown significant increase of cardiotoxicity [75].

At present neither the previous DBCG protocols nor the international literature has proved the benefit of inclusion of IMN in high risk- patients. Only one large trial (EORTC 22922/10925) has addressed this question (closed in 2002 after allocation of more than 4 000 patients). Results from this trial will not be available until 5-10 years after stop of accrual. On the basis of these considerations it was decided that in high risk patients, irrespective of lumpectomy or mastectomy, the target should not include the internal mammary nodes in patients with left-sided breast cancer whereas the target in patients with right-sided breast cancer if possible should include the internal mammary nodes (Figure 3). Following activation of these guidelines implemented in 2003, prospective registration of all radiotherapy data would allow a later analysis of the outcome in left-sided versus right-sided high risk patients with regard to tumour control, survival and cardiac morbidity. Currently techniques, which safely can assure minimal radiation dose to the lung and heart are under evaluation for routine use [76], as well as the large RACE study which is aimed to define the risk targets [77].

Since the beginning of 2000, registration of all radiotherapy data has been mandatory in all patients receiving radiotherapy, including information to the central registry why radiotherapy is not given if indicated (Tables I and II).

Radiotherapy in DBCG 2007

With the development of CT based treatment planning in all patients [78] much more detailed information about the coverage the target, dose homogeneity and of risk organs is available if electronically recorded. It is the ambition to do a nationwide quality control based on these registrations in the future as well as to continue to do national trials and answer new questions regarding optimal radiotherapy in early breast cancer.

Along with national screening programmes more and more patients will be eligible for lumpectomy and thereby the need for post-operative radiotherapy will increase. This is a big challenge at a time when the resources are limited. Therefore the accumulating evidence about the use of a moderate hypofractionation schedule after lumpectomy is of great interest [79,80], but due to the previous serious complications seen in patients treated in the 77 protocols the DBCG radiotherapy group has decided to be cautious before accepting such treatment as a standard. Thus the plan is to evaluate the hypofractionation schedule in a randomized setting with morbidity as the primary endpoint. The suggestion is to compare 40 Gy in 15 fractions in 3 weeks with 50 Gy in 25 fractions in 5 weeks in patients with node negative disease where only irradiation to residual breast is indicated. The morbidity evaluation will include cosmetic outcome, acute and late radiation effect in relation to volume irradiated, quality of treatment technique, interaction with other treatments and patient characteristics as well as identification of genetic profiles - in other words include all the knowledge we have gained from the past.

Another pertinent issue is partial irradiation after lumpectomy in selected low-risk patients. This is a new treatment approach, which is currently being studied in several randomized trials throughout the world [9,81].Similarly to the hypofractionation protocol described above, the DBCG radiotherapy group also plan a randomized study regarding partial versus whole breast irradiation, again with morbidity evaluation as the primary endpoint. The preparations for this protocol has been underway for a longer time in collaboration with the DBCG surgery group to obtain sufficient knowledge about which method to choose and to find which patients would be eligible [9,81].

Concluding remarks

During the 30 years time period of DBCG postoperative radiotherapy in breast cancer has moved from orthovoltage treatment based on direct clinical "set up" to megavoltage radiation with 2D and 3D treatment planning [1,78]. The close collaboration between physicists, radiobiologists and oncologists in the DBCG radiotherapy group has made it possible to design a treatment technique which was tested in the DBCG 82b and c trials and showed to be very effective with respect to tumour control and without major acute and late radiation morbidity. Through these studies, DBCG has contributed with important evidence about the role of postoperative radiotherapy in early breast cancer, and thereby also supported the current paradigm that optimal locoregional tumour control has influence on survival [82].

The DBCG structure with its scientific radiotherapy committee has given the basis for detailed studies of e.g., detailed evaluation of radiation morbidity in one or two centres in combination with national surveys and register based studies in a population, where the indications and guidelines for radiotherapy have been uniform. This has resulted in a large number of publications regarding clinical, radiobiological and physical aspects in radiotherapy of breast cancer as referred to in this paper. The structure of the radiotherapy group has also created the basis for several doctoral theses dealing with the scientific relevant issues related to radiotherapy in breast cancer [83–89].

The challenge for the DBCG radiotherapy group in the future will especially be the fast growing development in the technical possibilities in radiotherapy. This might help to design more focussed treatment planning in the individual patient with optimized tumour control and reduced radiation dose to critical tissues. In addition continuing work has to be done to tailor the radiation treatment to the extent of surgery and type of systemic therapy guided by the developed prognostic and predictive knowledge.
