**Abstract:** Rare diseases are increasingly recognized as a global public health priority. Governments worldwide currently provide important incentives to stimulate the discovery and development of orphan drugs for the treatment of these conditions, but substantial scientific, clinical, and regulatory challenges remain. Tafamidis is a first-in-class, disease-modifying transthyretin (TTR) kinetic stabilizer that represents a major breakthrough in the treatment of transthyretin amyloidosis (ATTR amyloidosis). ATTR amyloidosis is a rare, progressive, and fatal systemic disorder caused by aggregation of misfolded TTR and extracellular deposition of amyloid fibrils in various tissues and organs, including the heart and nervous systems. In this review, we present the successful development of tafamidis spanning 3 decades, marked by meticulous laboratory research into disease mechanisms and natural history, and innovative clinical study design and implementation. These efforts established the safety and efficacy profile of tafamidis, leading to its regulatory approval, and enabled post-approval initiatives that further support patients with ATTR amyloidosis.

**Keywords:** amyloidosis, cardiomyopathy, heart failure, transthyretin, treatment, Vyndaqel/Vyndamax

## Introduction

Rare diseases have an extensive impact on public health, despite their relatively low prevalence, and development of safe and effective treatments for rare disease is increasingly recognized as a global priority.<sup>1–3</sup> Rare diseases are designated as conditions occurring in fewer than 200,000 people in the USA<sup>4</sup> and 5 per 10,000 people in the EU.<sup>5</sup> Development of new therapies for rare diseases poses unique challenges, particularly from a clinical and regulatory perspective. To help mitigate the inherent difficulties, governments worldwide have enacted legislation to stimulate research and investment for orphan drugs targeting rare diseases.<sup>6,7</sup> Nonetheless, orphan drug discovery and development remains a daunting, risk-laden process, requiring substantial financial resources, incisive decision-making, and ingenuity to overcome obstacles related chiefly to minimal and, in some instances, lack of precedence in trial design and previously defined endpoints, small patient populations, and limited natural history of disease information.<sup>8</sup> Despite improvements in rare disease awareness, knowledge of pathophysiology, and legislative support, 95% of rare diseases do not have an approved treatment available in the USA.<sup>9</sup> Among the orphan drugs identified and investigated to date,

Correspondence: Adam Castaño  
Email Adam.Castano@pfizer.com

only a small fraction successfully emerge from rigorous testing in preclinical and clinical studies to gain regulatory approval each year.

The introduction of tafamidis, a first-in-class transthyretin (TTR) kinetic stabilizer, marked a critical breakthrough in the pharmacologic treatment of transthyretin amyloidosis (ATTR amyloidosis) with cardiomyopathy (ATTR-CM) or polyneuropathy (ATTR-PN). This rare systemic disorder is characterized by the extracellular aggregation of native and/or variant TTR into several distinct structures, including amyloid fibrils, which deposit in various tissues and organs.<sup>10</sup> The discovery and development of tafamidis for ATTR amyloidosis relied on a combination of meticulous laboratory investigation into the biological and chemical mechanisms underlying TTR aggregation, an innovative clinical development program, and determination and perseverance to support development of a treatment for patients with this rare disease.<sup>11</sup>

In this review, we highlight challenges associated with drug development in rare diseases and describe the translational success story of tafamidis. We identify research milestones that led to the development of the TTR kinetic stabilizer and its rational structure-based design. We summarize the essential findings of the pivotal tafamidis clinical trials that established the safety and efficacy profile of the drug and resulted in its regulatory approval for the treatment of ATTR-PN outside the US, and more recently, ATTR-CM in the US and globally. Finally, we present the ongoing work and challenges associated with rare disease amelioration in a population-driven health system.

## Drug Development in Rare Diseases

Rare diseases such as ATTR amyloidosis often lead to premature death, have a debilitating impact on patients' physical functioning, ability to work, and quality of life (QoL), and place a heavy emotional and financial burden on families.<sup>12,13</sup> Historically, therapeutic advances in rare diseases have been impeded by a poor understanding of their pathophysiology and natural history, and the high cost and complexity of conducting clinical investigations for diseases that affect small populations.<sup>14</sup>

## Advances

### Legislative and Regulatory Incentives

Nearly 40 years ago, the US Congress passed the Orphan Drug Act to encourage drug/biologic development for the treatment of rare diseases.<sup>12</sup> Subsequently, other governments worldwide similarly granted greater priority to rare

disease investigation and the development of orphan drugs.<sup>15</sup> Moreover, drug regulatory authorities in some countries have established designations (eg, fast-track and breakthrough therapy designations in the USA; Sakigake status in Japan) that allow for expedited development and review of select medications used for life-threatening diseases with an unmet medical need that demonstrate substantial benefit over existing therapies early in their clinical development. In the USA and elsewhere, tafamidis was granted orphan drug designation as well as fast-track and breakthrough therapy designations, and priority review, expediting the regulatory submission, review, and approval for this novel agent.

## Obstacles

Despite the regulatory programs intended to incentivize and support new treatments for rare diseases, many challenges remain in both the preclinical and clinical phases of rare disease research.<sup>12</sup>

### Limited Knowledge Base

Identification and characterization of appropriate in vitro and/or animal models for preclinical studies may be hindered by limited knowledge of disease pathophysiology and/or genetics. For clinical research, limited information and a poor understanding of the natural history of the disease makes selection of study endpoints difficult, and often impedes identification of the patient population best suited for assessment. These obstacles undoubtedly had an impact on the development of tafamidis, as the natural progression of ATTR amyloidosis and contributing environmental and genetic factors were not well understood when its clinical trial program was initiated.

### Low Clinical Trial Enrollment

According to research conducted by the Tufts Center for the Study of Drug Development (CSDD), patient recruitment for rare disease clinical trials is more challenging than for non-rare disease clinical trials due to substantially higher rates of screening and randomization failure.<sup>16</sup> Approximately 81% of screened patients were ineligible to enroll and 56% failed to be randomized in rare disease clinical trials, versus 57% and 36% of patients that fell into the categories in non-rare disease trials.

Several factors can hamper recruitment of patients for randomized controlled clinical trials of orphan drugs, including the small and widely dispersed patient populations affected, and disease heterogeneity. Patients with rare

diseases frequently receive various misdiagnoses over several years before a correct diagnosis is determined, increasing their disease burden and rendering some patients ineligible for clinical studies because of advanced disease.<sup>17,18</sup> Due to the low prevalence of rare diseases, a greater number of study sites are often needed globally to ensure adequate enrollment of even small numbers of patients, which may require additional support measures to reduce the burden of participation, eg, support for travel and/or lodging—all investments made without guarantee of success. Finally, there may be competing clinical trials for the same rare disease patients, limiting an already small number of patients eligible to enroll.

### Establishing a Suitable Trial Design

Designing trials with clinically appropriate methodology, including diagnostic procedures, dose(s), safety/efficacy endpoints, and a statistical analysis plan, is also particularly challenging for rare diseases. Determining appropriate diagnostic criteria for study eligibility and endpoints/outcomes for measuring treatment response for rare disease research is often complicated by the absence of accepted guidelines, validated prognostic factors, or indicators of disease progression. Limited patient numbers often preclude conduct of dose-ranging studies to characterize dose–response relationships useful for dose selection in future studies. In addition, efficacy endpoints must be selected that are clinically meaningful and in compliance with regulatory requirements for product approval; validated efficacy endpoints are not usually available for rare diseases. These endpoints may require analysis using innovative statistical methodology to compensate for the inclusion of relatively small patient populations. Maurer et al used the novel Finkelstein–Schoenfeld statistical method to analyze data for the primary endpoint in the pivotal tafamidis clinical trial in ATTR-CM to enable a robust analysis with the study’s relatively small sample size (detailed below).<sup>19</sup>

### Drug Development Cost

The economic burden associated with rare disease drug development is an additional possible deterrent, but few cost studies have been conducted. In one report, the clinical costs associated with developing orphan drugs were estimated to be half those associated with non-orphan drugs.<sup>20</sup> Using publicly available drug cost data, Jayasundara et al estimated that the out-of-pocket and capitalized (10.5% per year over the clinical phase testing

and regulatory approval period) clinical costs of each approved orphan drug were \$166 million and \$291 million in 2013 US dollars (or \$202 and \$354 million in 2020 US dollars), respectively.<sup>20</sup> However, the investigators acknowledged that additional research is needed to address factors that may substantially increase these costs, such as longer development timelines and lower probability of success for orphan drugs. Based on the Tufts CSDD research, the overall clinical and regulatory duration (ie, investigational new drug application to approval decision) for rare diseases is approximately 4 years longer than that for all diseases.<sup>16</sup> The prolonged timelines associated with orphan drug development can potentially increase costs.

## Systemic ATTR Amyloidosis: An Overview

ATTR amyloidosis is a rare, progressive, fatal disease caused by TTR misfolding, and aggregation and deposition of amyloid fibrils in the extracellular space of many tissues and organs, leading to end-organ degeneration. Strong genetic and pharmacologic evidence supports the amyloid hypothesis, ie, that TTR aggregation causes the death of post-mitotic tissue and is a critical triggering factor in the pathogenesis of ATTR amyloidosis–based degenerative diseases.<sup>21–23</sup> The pathogenesis of ATTR amyloidosis is associated with the destabilization of the tetrameric TTR protein. Tetramer dissociation is the rate-limiting step in TTR aggregation, which also requires subsequent monomer misfolding for misassembly to produce soluble misfolded TTR aggregates and insoluble aggregates, including amyloid fibrils (Figure 1).

In patients with autosomal dominant hereditary (or variant) ATTR amyloidosis (ATTRv), TTR tetramer destabilization is caused by the incorporation of pathogenic variant subunits into TTR heterotetramers, otherwise composed of wild-type TTR subunits. More than 150 *TTR* gene variants have been linked to amyloidosis in ATTRv, with varying degrees of penetrance and different tissue tropism.<sup>24–26</sup> Depending on the variant, ATTRv can present as a principal cardiomyopathy (ATTR-CM), a primary sensory, motor, and autonomic polyneuropathy (ATTR-PN), or a mixed phenotype that has cardiac and neurologic manifestations.<sup>27,28</sup> In patients with wild-type ATTR amyloidosis (ATTRwt), aging-associated tetramer dissociation, misfolding, and aggregation of TTR occurs in the absence of a genetic variant.<sup>29</sup> Other genetic and/or environmental

**Figure 1** The TTR amyloidogenic cascade. When destabilized by TTR pathogenic variants, the tetrameric protein TTR dissociates into monomers that misfold and misassemble into aggregates, including amyloid fibrils associated with transthyretin amyloidosis.

**Abbreviation:** TTR, transthyretin.

contributors to ATTRwt remain poorly understood, as does the tissue tropism. ATTRwt typically affects the heart and autonomic nervous system, particularly in older males, increasing the risk of cardiomyopathy, diastolic dysfunction, arrhythmias, and heart failure, but may also cause damage in other tissues/organs.

Although ATTR amyloidosis has been considered a rare disease, growing evidence suggests that the disease (particularly ATTRwt) may be more common than previously recognized. The prevalence of ATTRv varies by region due to allele frequencies that fluctuate by geographic distribution. Based on a comprehensive literature review, Schmidt et al estimated that hereditary ATTR-PN has a global prevalence of 10,186 persons (range, 5526–38,468).<sup>30</sup> In two recent cohort studies, the reported prevalence of the Val122Ile (p.Val142Ile) pathogenic variant, the most common in the USA, was approximately 3% among African Americans,<sup>31,32</sup> but disease penetrance is

still unknown.<sup>33</sup> Importantly, this genetic variant was found to be significantly associated with heart failure in carriers of either African or Hispanic/Latino ancestry.<sup>32</sup> Regions with endemic ATTRv have been reported in Japan, Portugal, Sweden, Cyprus, and Majorca, but the disease is now documented in 29 countries worldwide, including China, India, parts of Europe, and the USA.<sup>34</sup>

The prevalence of ATTRwt, the most common form of ATTR amyloidosis and an increasingly recognized cause of heart failure, has been difficult to establish. In a study of patients >60 years of age who had heart failure with preserved left ventricular ejection fraction and left ventricular wall thickness  $\geq 12$  mm, ATTRwt was identified by radionuclide scintigraphy in approximately 13% of screened patients.<sup>35</sup> Based on prospectively assessed myocardial biopsies conducted in patients with heart failure with preserved ejection fraction, Hahn et al recently reported a prevalence of ATTR cardiac amyloidosis of

10%, with ATTRwt observed in ~7%.<sup>36</sup> Recently, in a cohort of patients with heart failure and increased myocardial wall thickness (intraventricular septum >14 mm), approximately 20% of patients had ATTRwt when screened with radionuclide imaging.<sup>37</sup> In autopsy studies, the reported frequency of ATTRwt deposits has ranged from 10% to 25% of elderly patients.<sup>38–41</sup>

In clinical practice, both hereditary and sporadic forms of ATTR amyloidosis are challenging to identify, primarily due to the wide range of possible symptoms that potentially involve multiple organs.<sup>42</sup> ATTR-CM has been shown to be frequently misdiagnosed, or its diagnosis delayed until late in the disease course, because of low disease awareness/misperceptions of the disease and clinical features that overlap with more common etiologies of heart failure.<sup>17,43</sup> The expectancy that ATTR-CM predominantly occurs in men may reduce clinicians' suspicion of the disease in women. In a recent literature review,<sup>44</sup> among over 4500 patients with ATTR-CM, 17% were women; the proportions of women with variant ATTR-CM (29%) and undefined disease (18%) were higher than that of women with wild-type ATTR-CM (9%). Importantly, in the referenced review, some cardiac structural/functional differences, including lower interventricular septal and posterior wall thickness and higher left ventricular ejection fractions, were observed in women versus men across all ATTR-CM subtypes. Left ventricular wall thickness >12 mm is a recommended threshold for ATTR-CM diagnosis in both sexes, suggesting that women may be underdiagnosed as a result of their smaller cardiac anatomy. Additional research is warranted to better elucidate these differences and inform the identification of these patients in clinical practice.

The natural progression of ATTR amyloidosis is also not well documented. Nearly a decade ago, Ruberg et al prospectively evaluated morbidity and mortality in 29 patients with wild-type and Val122Ile (p.Val142Ile) variant ATTR-CM in the Transthyretin Amyloidosis Cardiac Study (TRACS).<sup>45</sup> They found no differences between patients with ATTRwt and ATTRv in clinical characteristics, biomarker levels, or echocardiographic variables at baseline. However, after approximately 16 months, patients with ATTRwt had significantly lower rates of mortality (22% vs 73%) and cardiovascular hospitalization (28% vs 64%) than patients with ATTRv. In patients with ATTRwt and ATTRv, median survival from diagnosis was approximately 3.6 and 2.2 years, respectively. Similarly, in untreated patients with ATTRwt and ATTRv cardiomyopathy, median overall

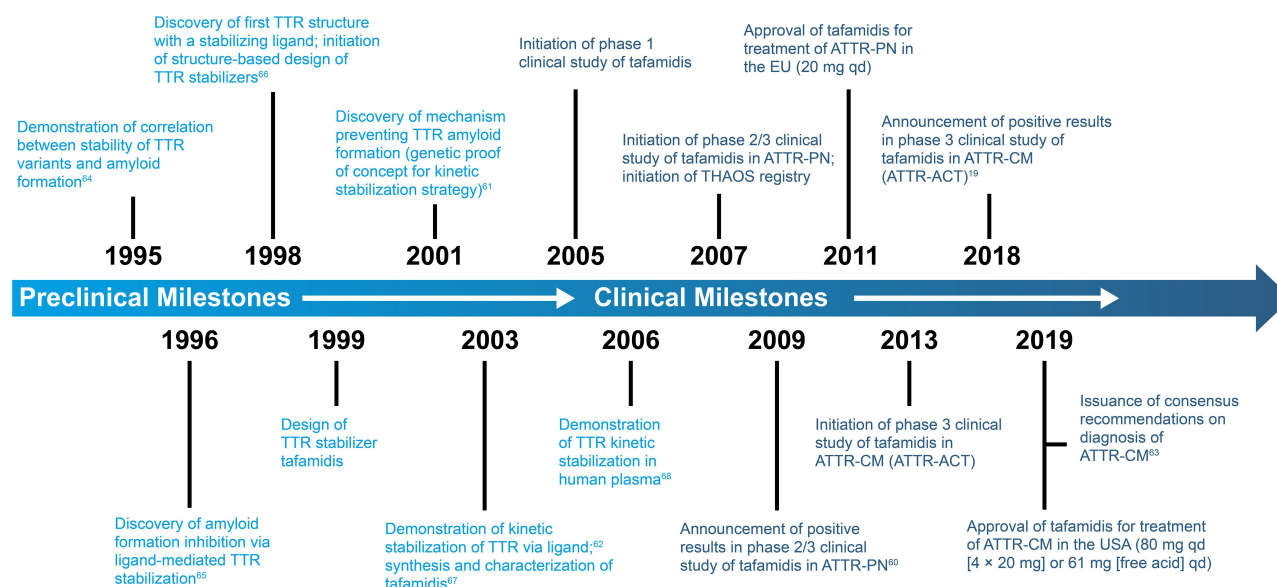

survival was recently estimated to be 3.6 and 2.5 years, respectively, after diagnosis.<sup>46,47</sup>

Until the introduction of tafamidis, treatment options available for ATTR amyloidosis were limited to symptomatic management or liver and/or heart transplantation. Because the liver produces more than 90% of TTR circulating in the bloodstream,<sup>48</sup> liver transplantation is a disease-modifying treatment for ATTRv. Liver transplantation is effective at slowing disease progression and improving survival in patients with the inherited form of the disease, particularly when performed in those with early-onset Val30Met (p.Val50Met) hereditary ATTR-PN.<sup>49–52</sup> However, in a subset of patients with ATTRv with both cardiac and neurologic manifestations, this surgical approach failed to prevent the progression of amyloid cardiomyopathy, potentially because circulating wild-type TTR continues to be deposited on existing variant TTR substrate, even in the absence of circulating variant TTR.<sup>53,54</sup> Liver transplantation is also associated with a first-year mortality rate of approximately 10%, due to vascular fragility in patients with ATTR amyloidosis, and the risk of complications in transplant patients overall and substantial chronic immunosuppression-related morbidity.<sup>50,52,55</sup>

Patients with ATTR amyloidosis involving severe cardiomyopathy may undergo combined liver and heart transplantation or heart transplant alone.<sup>56–58</sup> However, as with single-organ transplant, the benefits of liver/heart surgery can be offset by the risk of perioperative morbidity and mortality and the adverse effects of chronic immunosuppression.<sup>50–52</sup> As a result, heart transplantation, with or without combined liver transplantation, is generally considered a viable option primarily for selected patients with advanced ATTR-CM.<sup>33,59</sup> The limitations of organ transplantation and the scarcity of donor organs highlighted the need for development of pharmacologic therapies that block the amyloid cascade in patients with ATTR amyloidosis, and the need for early diagnosis and treatment to prevent advanced refractory disease.

## Research Milestones in the Development of TTR Kinetic Stabilizers

Findings from a broad network of studies played a critical role in the development of small molecules such as tafamidis designed to halt the progression of ATTR amyloidosis (Figure 2).<sup>19,60–68</sup> TTR (formerly called prealbumin) is a tetrameric protein that transports holo-retinol binding protein in the bloodstream and is a minor carrier of the

**Figure 2** Timeline of the major translational milestones in the development of the TTR kinetic stabilizer tafamidis. Superscript numbers refer to references.

**Abbreviations:** ATTR-ACT, Tafamidis in Transthyretin Cardiomyopathy Clinical Trial; ATTR, amyloidosis, transthyretin amyloidosis; ATTR-CM, transthyretin amyloid cardiomyopathy; ATTR-PN, transthyretin amyloid polyneuropathy; qd, once daily; THAOS, Transthyretin Amyloidosis Outcomes Survey; TTR, transthyretin.

thyroid hormone thyroxine ( $T_4$ ) in the blood.<sup>69–71</sup> In humans, most thyroid hormone is transported by albumin or thyroid-binding globulin in the blood, which leaves most  $T_4$ -binding sites on TTR unoccupied.<sup>72,73</sup> Although TTR is the major  $T_4$  carrier in the brain, most of the TTR tetramer is unliganded in the brain due to the  $T_4$  to TTR tetramer stoichiometry. These observations were important to the development of kinetic-stabilizing agents capable of binding to TTR at the unoccupied  $T_4$  binding sites.

In Portuguese families, in the early 1990s, Coelho et al observed that some carriers of the Val30Met (p.Val50Met) pathogenic variant either had no symptoms of ATTR-PN or had uncharacteristically mild symptoms.<sup>74</sup> Gene sequencing studies revealed that these individuals were compound heterozygotes expressing the disease-causing Val30Met (p.Val50Met) variant on one allele and a Thr119Met (p.Thr139Met) variant on the second allele (instead of wild-type TTR), conferring protection against ATTR-PN.<sup>74</sup> Incorporation of Thr119Met (p.Thr139Met) subunits into tetramers otherwise comprised of disease-associated subunits increased the kinetic stability of the tetramer, which slowed tetramer dissociation and suppressed disease.<sup>61,62,74,75</sup> It was subsequently discovered that the dissociation barrier (ie, the energy required for the formation of misfolded monomers) increased proportionally with each Thr119Met (p.Thr139Met) subunit incorporated into a tetramer, demonstrating that increasing the kinetic barrier associated with misfolding can stabilize

the native tetramer state and slow or prevent TTR aggregation, thus ameliorating ATTR amyloidosis.<sup>76</sup>

Based on a thorough investigation into the mechanisms underlying TTR aggregation, researchers were able to establish that dissociation of the native TTR tetramer was the slowest and first step of the aggregation cascade or process.<sup>61,62,76–82</sup> The observed efficiency of TTR aggregation after TTR monomer misfolding also helped focus drug discovery on blocking TTR aggregation before rate-limiting tetramer dissociation.<sup>83</sup> This milestone led to the hypothesis that small-molecule ligand stabilization could prevent TTR dissociation into monomers and thereby block all TTR misfolding and aggregation, including amyloid fibril formation. Thus, the concept of TTR small-molecule “kinetic stabilizers” emerged, ie, small molecules capable of selectively binding to native TTR tetramer over the dissociative transition state, slowing tetramer dissociation dramatically, to inhibit TTR aggregation. Importantly, the kinetic stabilizer strategy is conservative, in that its clinical success does not require an understanding of which aggregate structure(s) are driving the degenerative phenotypes, because kinetic stabilizer treatment reduces the concentration of all misfolded TTR structures and aggregates derived from newly synthesized TTR.

## Drug Design

Based on the kinetic stabilization observations, a strong rationale was constructed for the development of small-molecule kinetic stabilizers that bind to the largely unoccupied  $T_4$

binding pockets and stabilize the native TTR tetramer as potential pharmacotherapy to prevent the progression of ATTR amyloidogenesis.<sup>76</sup> Structure-based design and biochemical assays were used to iteratively improve the potency of the kinetic stabilizers in several structurally distinct small-molecule families or chemotypes that inhibited TTR aggregation by kinetically stabilizing the tetrameric energetic ground state of TTR.<sup>62,76,84,85</sup> The prioritization of candidate kinetic stabilizers was based on assessments of stabilizer performance under denaturing conditions,<sup>62</sup> TTR aggregation inhibition as a function of kinetic stabilizer concentration under acidic conditions,<sup>76,78,79,84</sup> and the degree of selective binding of the kinetic stabilizer to TTR in human plasma.<sup>86</sup>

Candidate TTR kinetic stabilizers from repurposing efforts included several nonsteroidal anti-inflammatory drugs (NSAIDs), such as flufenamic acid, diflunisal, meclofenamic acid, and mefenamic acid.<sup>68,85,87</sup> However, NSAID activity was considered potentially detrimental in candidate TTR kinetic stabilizers because cyclooxygenase inhibition should be avoided in patients with ATTR-CM, who often have renal blood flow impairment.<sup>85</sup> In addition, the risk of serious gastrointestinal, renal, and cardiac toxicity with chronic use of NSAIDs, particularly in aging populations with other medical conditions, weighed against their development for the treatment of ATTR amyloidosis.<sup>88</sup>

Medicinal chemistry and structure-activity data on novel kinetic stabilizer chemotypes focused attention on the benzoxazole carboxylic acids. The benzoxazole derivative 2-(3,5-dichloro-phenyl)-benzoxazole-6-carboxylic acid, or tafamidis, was identified as an oral candidate capable of substantially slowing the rate-limiting step in the TTR amyloid cascade and was selected for clinical development.<sup>89</sup> Tafamidis lacked NSAID activity, and exhibited an acceptable toxicity profile and no thyroid-related metabolic effects.<sup>89</sup>

## Tafamidis Pharmacodynamic/ Pharmacokinetic Studies

In nonclinical *in vitro* and *ex vivo* experiments, tafamidis bound with high selectivity and affinity, and negative cooperativity, to recombinant wild-type TTR and both wild-type and variant forms of TTR in human plasma.<sup>89,90</sup> This compound was shown to dose-dependently kinetically stabilize TTR under denaturing and physiological conditions.<sup>85</sup> Tafamidis exhibited comparable potency in inhibiting tetramer dissociation of wild-type native TTR and a broad range of TTR variants,

including the two most common amyloidogenic variants, Val30Met (p.Val50Met) and Val122Ile (p.Val142Ile).<sup>89</sup>

Tafamidis was shown to stabilize TTR variants *ex vivo* using an immunoturbidometric assay in nonclinical and clinical studies.<sup>89</sup> Evidence from nonclinical studies suggested that a tafamidis:TTR stoichiometry of 1–1.5:1 was sufficient to stabilize TTR and reduce TTR tetramer dissociation in human plasma.<sup>91</sup> In two Phase 1, randomized, double-blind, ascending dose tolerance studies conducted in healthy volunteers receiving single oral doses of tafamidis (up to 120 mg or 480 mg), increasing plasma tafamidis:TTR stoichiometry was associated with increases in mean percent TTR stabilization.<sup>91</sup> In an *ex-vivo* study, the immunoturbidometric assay was used to compare tetrameric TTR stability in plasma samples from patients with ATTR amyloidosis in the absence or presence of tafamidis.<sup>91</sup> Tafamidis increased the stability of the native tetrameric structure of all but 1 of the 27 amyloidogenic, non-Val30Met (p.Val50Met) and non-Val122Ile (p.Val142Ile) TTR variants analyzed. Finally, a >73% reduction in TTR tetramer dissociation rate was observed in patients with ATTRwt treated with tafamidis 20 mg orally once daily versus untreated age-matched controls; in the tafamidis-treated patients, the tafamidis concentration in plasma was strongly correlated with the rate of tetramer dissociation.<sup>90</sup>

In addition to the ability to bind TTR tetramers with high affinity and selectivity to slow TTR tetramer dissociation, tafamidis needed to demonstrate appropriate pharmacokinetic properties prior to investigation in clinical trials. In clinical investigations conducted in healthy volunteers, tafamidis meglumine 20 mg administered orally, once daily, as soft gelatin capsules exhibited a favorable pharmacokinetic profile.<sup>91,92</sup>

## The Tafamidis Clinical Trial Program

A brief review of the efficacy and safety profile of tafamidis demonstrated in Phase 2 and 3 clinical investigations is provided in this section, with additional information on the studies' methodology and efficacy outcomes summarized in Table 1.

## Transthyretin Amyloid Polyneuropathy

In 2011, in the EU, tafamidis became the first medication approved for the treatment of patients with ATTR-PN based on the clinical efficacy/safety profile demonstrated in polyneuropathy clinical trials.<sup>93</sup> It is currently approved as treatment for this disease in more than 40 countries worldwide.<sup>94</sup>

**Abbreviations:** ATTR-ACT, Tafamidis in Transthyretin Cardiomyopathy Clinical Trial; ATTR-CM, transthyretin amyloid cardiomyopathy; ATTR-PN, transthyretin amyloid polyneuropathy; ATTRv, variant transthyretin amyloidosis; BL, baseline; CI, confidence interval; CV, cardiovascular; EE, efficacy evaluable; ITT, intent-to-treat; KPS, Karnofsky Performance Status score; LS, least-squares; mITT, modified intent-to-treat; mo, month; N/A, not available; NIS-LL, Neuropathy Impairment Score in the Lower Limbs; NT-proBNP, N-terminal pro-B-type natriuretic peptide; NYHA, New York Heart Association; pts, patients; SD, standard deviation; TQoL, Total Quality of Life score from the Norfolk Quality of Life-Diabetic Neuropathy questionnaire; TTR, transthyretin; wk, week; y, year.

A better understanding of the natural history of the polyneuropathy phenotype allowed testing in this population first, while knowledge of ATTR-CM was evolving. Moreover, testing of a 20-mg dose of tafamidis preceded testing of higher doses as more information was obtained on potential dose-dependent effects on TTR tetramer stabilization.

In a Phase 2, open-label, single-treatment-arm study, 21 patients with ATTRv due to non-Val30Met (p.Val50Met) pathogenic variants (excluding Val122Ile [p.Val142Ile]) received tafamidis 20 mg once daily for 12 months.<sup>95</sup> TTR was stabilized in 95% of 19 patients with evaluable data after 6 weeks of treatment, and 100% of 17 patients with non-missing data after 12 months. Mean changes in the health-related QoL from baseline to months 6 and 12 were negligible, and overall nutritional status was maintained over the 12-month treatment period, with some variation between months 6 and 12.

In the pivotal double-blind trial (ClinicalTrials.gov identifier: NCT00409175), 128 patients with early-stage Val30Met (p.Val50Met) disease were randomized to receive

tafamidis 20 mg or placebo for up to 18 months.<sup>60</sup>

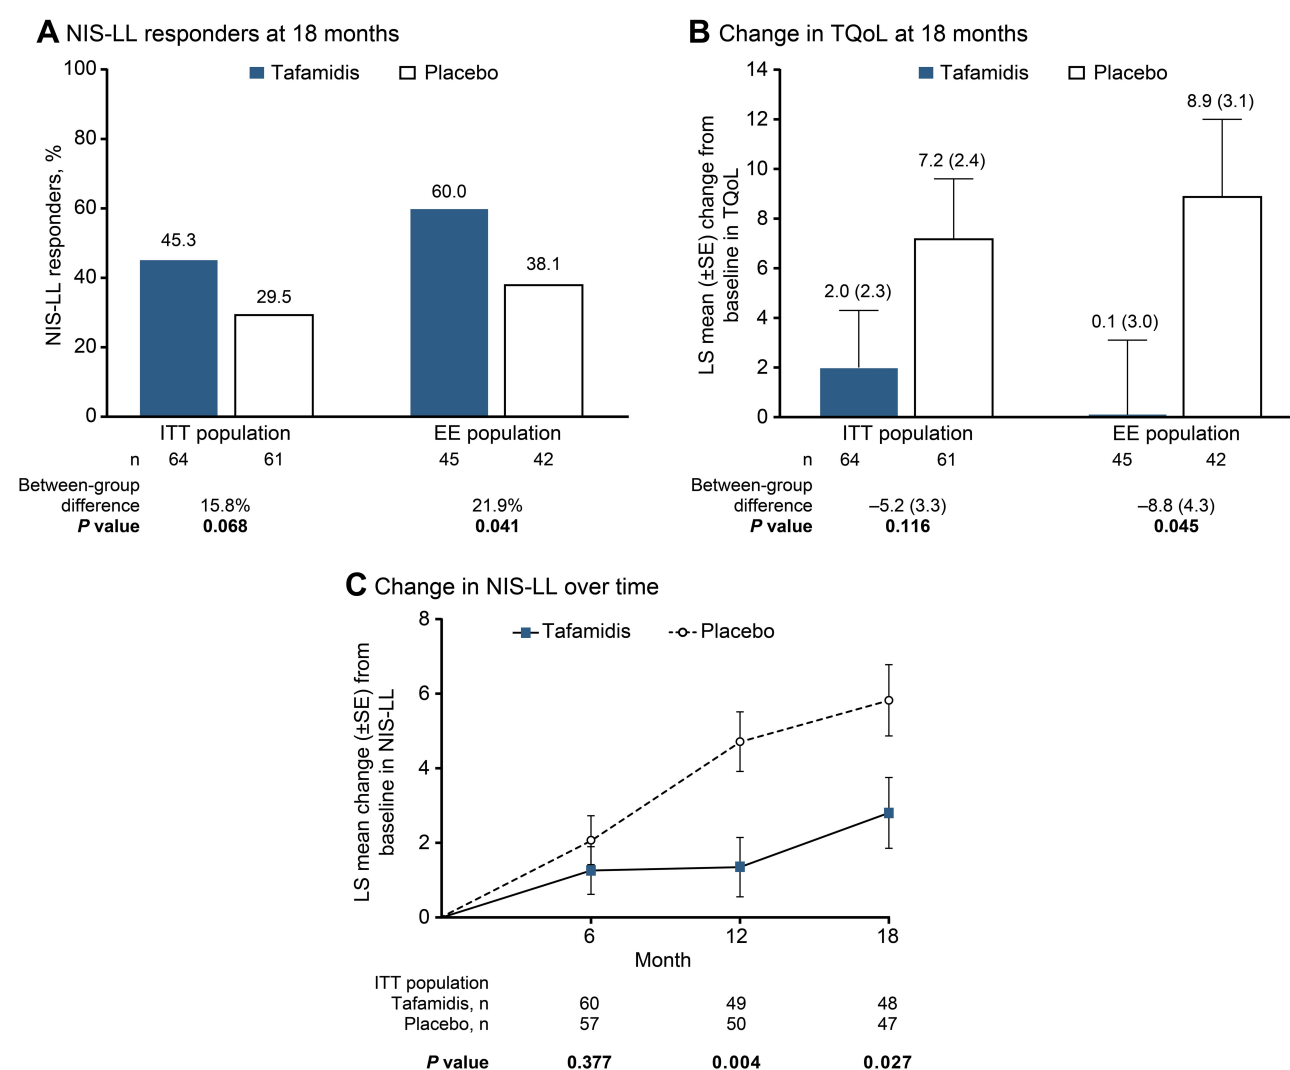

A significant difference between tafamidis and placebo was not achieved for the coprimary efficacy endpoints in the primary analysis of the intent-to-treat population (Figure 3A, 3B). Based on these results, tafamidis was denied regulatory approval in the USA. However, in this study, patients receiving tafamidis had a significant reduction in neurologic deterioration at both months 12 and 18 compared with patients receiving placebo (Figure 3C). At month 18, tafamidis-treated patients had 52% less neurologic deterioration than patients who received placebo. The latter clinical benefits were sufficient to warrant approval of the drug by regulatory authorities in the EU, Japan, and other countries. The incidences of serious adverse events and adverse events leading to discontinuation from the study were similar in the tafamidis and placebo groups over this time period (Table 2A). It is worth noting that the selection of endpoints for this study, which was among the first randomized controlled studies conducted in a population with this rare

disease, was based on the limited natural history information available at the time, including estimates of disease progression and clinically meaningful treatment effects. The outcomes from this study and evolving understanding of the disease substantially informed the design of other ATTR amyloidosis treatment trials.

Patients who continued to receive tafamidis in an open-label extension (ClinicalTrials.gov identifier: NCT00791492) had stable rates of change in scores measuring neurologic function and QoL over 30 months.<sup>96</sup> Patients switching from placebo to tafamidis showed significant reductions in neurologic and QoL deterioration in the extension trial, but treatment benefits were not as great as in patients who initiated

tafamidis earlier. Adverse event rates were similar in both groups, and no patients died during the extension study or had adverse events that were life-threatening or led to study discontinuation.

Evidence from open-label extension studies providing data from up to 8.5 years of treatment (ClinicalTrials.gov identifiers: NCT00409175, NCT00791492, NCT00630864, and NCT00925002) has further supported the sustained beneficial effects of tafamidis in delaying disease progression and demonstrates tafamidis tolerability in ATTR-PN.<sup>98–100</sup> Additionally, evaluation of mortality in patients receiving long-term tafamidis therapy in prospective interventional trials showed approximately 75% and 85% of patients with

**Figure 3** (A) Proportion of NIS-LL responders<sup>a</sup> at month 18 in the ITT<sup>b</sup> and EE populations. **Table 2** Adverse Events Reported by Treatment Group in Pivotal Randomized Controlled Trials of Tafamidis in (A) ATTR-PN<sup>60</sup> and (B) ATTR-CM (ATTR-ACT)<sup>19</sup>

<b>(A) ATTR-PN</b>		
<b>Adverse Event</b>	<b>No. of Patients (%)</b>	
	<b>Tafamidis (n = 65)</b>	<b>Placebo (n = 63)</b>
≥1 adverse event	60 (92.3)	61 (96.8)
≥1 serious adverse event	6 (9.2)	5 (7.9)
Discontinued treatment due to adverse event	4 (6.2)	3 (4.8)
<b>(B) ATTR-CM (ATTR-ACT)</b>		
<b>Adverse Event</b>	<b>No. of Patients (%)</b>	
	<b>Pooled Tafamidis (n = 267)</b>	<b>Placebo (n = 177)</b>
≥1 adverse event	260 (98.5)	175 (98.9)
≥1 serious adverse event	199 (75.4)	140 (79.1)
≥1 severe adverse event	164 (62.1)	114 (64.4)
Discontinued treatment due to adverse event	56 (21.2)	51 (28.8)
Temporarily discontinued due to adverse event	53 (20.1)	46 (26.0)

**Note:** All adverse events were treatment emergent (all causality).

**Abbreviations:** ATTR-ACT, Tafamidis in Transthyretin Cardiomyopathy Clinical Trial; ATTR-CM, transthyretin amyloid cardiomyopathy; ATTR-PN, transthyretin amyloid polyneuropathy.

ATTR-PN caused by non-Val30Met (p.Val50Met) and Val30Met (p.Val50Met) pathogenic variants were alive at 8 and 9 years, respectively, after receiving their first tafamidis dose.<sup>99</sup> None of the 11 deaths reported in the latter analysis were related to tafamidis treatment; four of the deaths occurred following liver transplantation.

When comparing survival among patients with Val30Met (p.Val50Met) ATTR-PN treated with tafamidis or undergoing liver transplantation to untreated controls in an observational multihospital cohort study, Coelho et al found that both tafamidis and surgery provided survival benefits compared with natural disease progression.<sup>101</sup> Tafamidis was associated with a significant reduction in mortality risk of 63% versus liver transplantation in patients with early-onset disease. In a recent study comparing the effects of tafamidis and liver transplantation in patients with hereditary ATTR-PN, patients receiving treatment with tafamidis had significantly longer overall survival compared with those undergoing surgery.<sup>102</sup>

## Transthyretin Amyloid Cardiomyopathy

Tafamidis is the first pharmacotherapy approved to treat patients with wild-type or hereditary ATTR-CM, with approval in the USA and Japan received in 2019, and the EU in 2020. Currently available for the treatment of ATTR-CM in nearly 50 countries worldwide, tafamidis is the only pharmacotherapy shown to reduce all-cause mortality and cardiovascular-related hospitalizations in patients with ATTR-CM.<sup>103</sup>

Evidence of its safety and efficacy in ATTR-CM was provided in Phase 2 and 3 clinical trials. In a post hoc analysis of findings from the aforementioned Phase 2, open-label ATTR-PN study,<sup>95</sup> Damy et al assessed the efficacy and safety of tafamidis 20 mg daily, administered for 12 months, on cardiac structure and function in 21 patients with non-Val30Met (p.Val50Met) and non-Val122Ile (p.Val142Ile) disease.<sup>104</sup> At baseline, a majority of patients presented with signs/symptoms of cardiac involvement, including New York Heart Association (NYHA) class II heart failure (n = 11), conduction abnormalities (n = 13), N-terminal pro-B-type natriuretic peptide (NT-proBNP) >300 pg/mL (n = 14), and/or interventricular septal thickness >12 mm (n = 17); mean left ventricular ejection fraction was 60.3% in this study population. During the 12-month tafamidis treatment period, patients had no clinically meaningful deterioration in conduction, left ventricular thickness, or left ventricular systolic or diastolic function, and NT-proBNP levels were stable. Moreover, echocardiographic and electrocardiographic findings showed no clinically relevant changes with tafamidis over time. The cardiac findings from this Phase 2 tafamidis trial in patients with ATTR-PN provided critical information and momentum for the development of additional ATTR-CM studies.

In a Phase 2, open-label trial conducted in 35 patients with early-stage wild-type ATTR-CM (ClinicalTrials.gov identifier: NCT00694161), tafamidis 20 mg daily was administered for 12 months to evaluate its safety and efficacy in altering disease progression.<sup>105,106</sup> This was the first clinical assessment of tafamidis in patients with ATTR amyloidosis nearly exclusively of the cardiac phenotype. Patients had a median disease duration of 56 months, and 97% had mild-to-moderate heart failure (NYHA class I–II). During the treatment period, 89% of patients achieved TTR stabilization and 71% had preserved NYHA functional status. After 12 months, 10% had discontinued tafamidis prematurely, 6% died, 23% were hospitalized due to cardiovascular events, and 48% demonstrated clinical progression. Tafamidis was generally well tolerated, with no significant increase in

NT-proBNP or clinically relevant changes in echocardiographic findings observed.

To further evaluate the effect of tafamidis on survival in earlier-stage ATTR-CM, Sultan et al compared survival data from tafamidis-treated patients in the above-mentioned open-label trial<sup>105</sup> with those from untreated patients with ATTR-CM in the TRACS population,<sup>45</sup> excluding patients with NYHA class  $\geq$ III to ensure patients had comparable baseline disease severity.<sup>106</sup> In this post hoc analysis, patients with either wild-type or Val122Ile (p.Val142Ile) genotypes treated with tafamidis had a significantly longer time to death than untreated patients. These encouraging findings suggested the need for further exploration of tafamidis in a larger controlled clinical study of patients with ATTR-CM.

In the pivotal, randomized controlled Tafamidis in Transthyretin Cardiomyopathy Clinical Trial (ATTR-ACT; ClinicalTrials.gov identifier: NCT01994889), Maurer et al compared the safety and efficacy of tafamidis (20 mg and 80 mg daily) versus placebo after 30 months of treatment in 441 patients with wild-type and variant ATTR-CM.<sup>19</sup> Investigation of the effects of the tafamidis 80 mg dose in this study was supported by two salient findings from previous studies conducted in healthy volunteers: first, the 80 mg dose

was shown to provide near maximal TTR stabilization;<sup>91</sup> and second, a supratherapeutic dose of tafamidis 400 mg was shown to be well tolerated.<sup>107</sup> The 20 mg and 80 mg tafamidis dose groups were pooled and compared with placebo for analysis of primary and secondary efficacy endpoints. This pooling of the active treatment groups was conducted in agreement with US and EU regulatory authorities to address the small number of patients with this rare disease.

The primary analysis from ATTR-ACT utilized the Finkelstein–Schoenfeld statistical method, which demonstrated that tafamidis treatment was superior to placebo in reducing the hierarchical combination of all-cause mortality and frequency of cardiovascular-related hospitalization over 30 months (Figure 4). This statistical method was selected because it increases the power and sensitivity of analyses of smaller patient populations and prioritizes assessment of mortality while also addressing morbidity.<sup>108</sup>

In addition, treatment with tafamidis reduced the risk of all-cause mortality and cardiovascular-related hospitalization by 30% and 32%, respectively, versus placebo.<sup>19</sup> The number needed to treat with tafamidis to prevent one death was seven and a half over the 2.5-year treatment period, and the number needed to treat to prevent one hospitalization per year was four. These benefits were consistent across the prespecified

**Figure 4** All-cause mortality and frequency of cardiovascular-related hospitalizations (primary efficacy analysis) in patients with ATTR-CM treated with tafamidis versus placebo in ATTR-ACT.<sup>19</sup> The combined primary endpoint was hierarchically assessed using the Finkelstein–Schoenfeld method.  $P < 0.001$ .

**Abbreviations:** ATTR-ACT, Tafamidis in Transthyretin Cardiomyopathy Clinical Trial; ATTR-CM, transthyretin amyloid cardiomyopathy.

subgroups analyzed in ATTR-ACT (ie, 80 mg vs 20 mg dose; ATTRv vs ATTRwt; and NYHA class I or II vs class III), except the frequency of cardiovascular-related hospitalizations was higher with tafamidis than placebo in patients with NYHA class III. The investigators speculated that the higher hospitalization rate in the latter subgroup of tafamidis-treated patients was a consequence of their longer survival during a period of more severe disease. Thus the greatest benefits were observed when tafamidis was administered earlier in the course of the disease. Overall, patients in the tafamidis group also demonstrated significant reductions in the decline of functional capacity, health status, and QoL compared with those in the placebo group. Similar incidence and types of adverse events were reported across the pooled tafamidis and placebo groups in the study (Table 2B).

In ATTR-ACT, median overall survival was not reached in either the placebo or pooled tafamidis treatment groups; 57.1% and 70.5% of patients in these groups, respectively, survived at 30 months. Therefore, a survival extrapolation analysis was conducted to estimate patients' median overall survival beyond the study's 30-month duration.<sup>109</sup> According to this extrapolation analysis, conducted based on National Institute for Health and Care Excellence technical support guidelines, the estimated median overall survival was 17.5 months longer with tafamidis compared with placebo.<sup>109</sup>

ATTR-ACT was not designed to assess the relative efficacy of each tafamidis dose. However, the efficacy of the individual tafamidis 20 mg and 80 mg doses was recently assessed over a longer treatment period in a combined analysis of 30-month data from ATTR-ACT<sup>19</sup> and interim data from the ongoing, open-label, long-term extension of ATTR-ACT<sup>110</sup> (ClinicalTrials.gov identifiers: NCT01994889; NCT02791230). In ATTR-ACT, both tafamidis doses significantly reduced the combination of all-cause mortality and cardiovascular-related hospitalizations over 30 months versus placebo.<sup>19</sup> After a median of 51 months' follow-up, patients initially treated with tafamidis 80 mg had a significantly reduced risk of all-cause mortality compared with those initiated on the 20-mg dose.<sup>110</sup>

## Development of a Single Capsule Tafamidis Formulation

After its regulatory approval for ATTR-PN in 2011, tafamidis was available as 20-mg tafamidis meglumine capsules. In ATTR-ACT, patients received tafamidis in doses of 20 mg (tafamidis meglumine 1 × 20 mg and 3 × placebo) or 80 mg

(tafamidis meglumine 4 × 20 mg).<sup>19</sup> Because the 80-mg tafamidis dose was under investigation (and subsequently approved in several countries) for the treatment of ATTR-CM, researchers sought to develop a single tafamidis meglumine 80-mg capsule for patient convenience. However, technical limitations (ie, concentration-dependent gelling in aqueous media) precluded the development of this formulation. Other single, solid, oral dosage formulations were therefore evaluated as more convenient options to the tafamidis meglumine 80-mg dose.

The tafamidis 61-mg free acid capsule formulation was selected on the basis of pharmacokinetic/safety results from several single-dose tafamidis studies, and simulations conducted to select the appropriate dose. This formulation is currently approved for the treatment of ATTR-CM in the EU, USA, and in many other countries worldwide. The tafamidis meglumine salt and free acid formulations have the same bioactive moiety (tafamidis) and biologic effects. In an open-label, multiple-dose, Phase 1 study, tafamidis 61-mg free acid capsules were shown to be bioequivalent (as measured by area under the concentration–time profile and maximum observed concentration) to tafamidis meglumine 80-mg (4 × 20-mg) capsules after 7 days of repeated oral dosing under fasted conditions in healthy volunteers.<sup>111</sup> Both formulations also demonstrated an acceptable safety/tolerability profile in this population, with no serious adverse events or deaths reported. Importantly, as described above, in the ongoing open-label, long-term extension study of ATTR-ACT (ClinicalTrials.gov identifier: NCT02791230), all patients were successfully transitioned from tafamidis 80 mg or 20 mg (after a median of 39 months) to the new, single-capsule tafamidis free acid 61 mg formulation.<sup>110</sup>

## Real-World Evidence

Many reports on ATTR amyloidosis have been published from studies conducted in a small number of centers within a single country because of the rare nature of the disease.<sup>112–120</sup> Rare disease registries allow for the investigation of disease states and treatments in a real-world setting over longer periods of follow-up in generally larger and more heterogeneous global populations.<sup>121</sup> The Transthyretin Amyloidosis Outcomes Survey (THAOS; ClinicalTrials.gov identifier: NCT00628745), established in 2007, is the largest ongoing, global, longitudinal observational survey of patients with ATTR amyloidosis, including both inherited and wild-type disease, and asymptomatic patients with *TTR* mutations. The primary objective of this survey is to better understand and characterize the natural history of ATTR

amyloidosis by studying a large and heterogeneous patient population. THAOS is currently the largest global database on ATTR amyloidosis, with findings that have reinforced the genetic and phenotypic heterogeneity of the disease worldwide.<sup>22,122–124</sup>

THAOS also provides data for real-world analyses of the safety and effectiveness of treatment for ATTR amyloidosis. As part of a comprehensive safety summary of tafamidis in ATTR-PN, safety was evaluated in 661 patients in THAOS who were treated with tafamidis 20 mg/day (data cut: 3 January 2017).<sup>125</sup> Data suggested that tafamidis was generally safe and well tolerated; after exposure to tafamidis for a mean of 28 months, 38% and 15% of patients experienced treatment-emergent adverse events and treatment-emergent serious adverse events, respectively. In an effectiveness analysis of data from THAOS (data cut: 6 January 2015), Munday et al compared outcomes in 252 tafamidis-treated patients with a predominantly neurological phenotype (93% with Val30Met [p.Val50Met]) with those in 167 matched untreated patients over a 2-year period.<sup>126</sup> Tafamidis-treated patients had significantly lower rates of deterioration in neurologic function and in worsening of QoL than untreated patients, suggesting a slower rate of disease progression. Seven deaths occurred in the untreated group, and no deaths occurred in the tafamidis-treated group. The real-world evidence from THAOS is consistent with findings from tafamidis clinical trials,<sup>60,96</sup> supporting the overall safety and effectiveness of this first-in-class kinetic stabilizer in ATTR-PN.

As evidence from real-world studies accrues, data will also become available on the use of tafamidis in ATTR amyloidosis with cardiac manifestations. Among the first examples is a recent retrospective observational study of patients with ATTR-CM treated with tafamidis at the Oregon Health & Science University.<sup>127</sup> In this real-world population, clinical outcomes, including mortality rates, were found to be comparable to those previously reported in ATTR-ACT.<sup>19</sup>

## Discussion

Knowledge of ATTR amyloidosis has advanced over the past several decades, but unanswered questions about its pathophysiology, etiology, natural history, and prevalence have presented unique challenges and risks when considering drug development and clinical trial design. Although discovery of the complex underlying mechanisms of ATTR amyloidosis has involved decades of detailed investigation,

it is far from complete. However, researchers' identification of TTR tetramer dissociation as the rate-limiting step in ATTR amyloidogenesis proved to be a critical breakthrough, leading to the hypothesis that a small-molecule kinetic stabilizer could be developed to slow tetramer dissociation, stop the aggregation of newly biosynthesized TTR, and halt disease progression. This mechanistic laboratory research culminated in the discovery of tafamidis, the TTR kinetic stabilizer rationally and precisely designed to arrest the amyloid cascade in patients with TTR amyloidosis. As summarized in this review, an extensive series of laboratory and clinical research programs and regulatory milestones subsequently paved the way for the clinical success of this novel treatment (Figure 2; Table 1).

Important insights have been gained from the pioneering work involved in the discovery and development of tafamidis, including the need to adopt a tenacious and thoughtful approach to the clinical trial program that keeps pace with research findings on the disease itself. Knowledge garnered from facing and overcoming obstacles informed not only tafamidis trial design and conduct but also helped provide a roadmap for future experimental agents in rare diseases. For example, the original protocol of the ATTR-ACT study was amended to include radionuclide scintigraphy for eligibility assessment based on evolving diagnostic recommendations. This non-invasive scanning technique subsequently became more commonly used as its high sensitivity and specificity in diagnosing ATTR-CM was confirmed in both clinical research and practice settings. In addition, collaboration with patient advocacy groups and genetic testing companies were important to support and ensure recruitment of sufficient numbers of participants with ATTR amyloidosis in tafamidis clinical trials, which will continue to strengthen research initiatives for subsequent generations of amyloidosis therapies.

Clinicians and health systems have typically focused on conditions affecting large populations, allowing rare diseases to remain unrecognized until they have progressed to late stages. To help facilitate the early, rapid, and accurate identification of ATTR-CM, the Amyloidosis Research Consortium published diagnostic recommendations in 2019, including “red flag” signs and symptoms and a detailed diagnostic algorithm for patients with suspected disease.<sup>63</sup> The advantages of noninvasive myocardial scintigraphy in the diagnosis of ATTR-CM—high specificity and sensitivity for ATTR-CM, imaging simplicity, ease of access, and lower cost versus endomyocardial biopsy—support broader use of this technique, which is expected to improve diagnosis, and potentially lead to earlier diagnosis of the disease.<sup>63</sup> Moreover, work is

ongoing on artificial intelligence and machine learning models using electronic health records and imaging technologies capable of identifying patients at risk of having ATTR-CM.<sup>128</sup> These models may eventually be used to increase the index of suspicion of ATTR-CM to support prompt diagnosis of the disease in the clinical practice setting. Finally, educational initiatives and research/decision support tools are in development for systematic adoption by health systems to help ensure that patients with rare diseases such as ATTR-CM are not overlooked.

Despite newly available diagnostic algorithms, imaging modalities, technological innovations, and population health initiatives, there remains a need for greater awareness of ATTR amyloidosis among clinicians and patients, and more informed screening to identify at-risk patients and ensure earlier identification and use of a disease-modifying treatment. The availability of pharmacologic treatments such as tafamidis will encourage clinicians to consider ATTR amyloidosis in their differential diagnoses when patients present with possible manifestations of amyloid disease, improving the formerly very poor prognosis associated with this rare disease.

## Abbreviations

ATTR-ACT, Tafamidis in Transthyretin Cardiomyopathy Clinical Trial; ATTR amyloidosis, transthyretin amyloidosis; ATTR-CM, transthyretin amyloid cardiomyopathy; ATTR-PN, transthyretin amyloid polyneuropathy; ATTRv, variant transthyretin amyloidosis; ATTRwt, wild-type transthyretin amyloidosis; BL, baseline; CI, confidence interval; CV, cardiovascular; EE, efficacy evaluable; ITT, intent-to-treat; KPS, Karnofsky Performance Status score; LS, least-squares; mITT, modified intent-to-treat; mo, month; N/A, not available; NIS-LL, Neuropathy Impairment Score in the Lower Limbs; Norfolk QoL-DN, Norfolk Quality of Life-Diabetic Neuropathy questionnaire; NSAID, nonsteroidal anti-inflammatory drugs; NT-proBNP, N-terminal pro-B-type natriuretic peptide; NYHA, New York Heart Association; pts, patients; QoL, quality of life; SD, standard deviation; SE, standard error; T<sub>4</sub>, thyroxine; THAOS, Transthyretin Amyloidosis Outcomes Survey; TQoL, Total Quality of Life score from the Norfolk Quality of Life-Diabetic Neuropathy questionnaire; TRACS, Transthyretin Amyloidosis Cardiac Study; TTR, transthyretin; wk, week; y, year.

## Disclosure

Medical writing support for this article was provided by Donna McGuire of Engage Scientific Solutions and was funded by Pfizer. AC, MB, SR, JS, MBS, and SST are full-time

employees of Pfizer and may hold Pfizer stock and/or stock options. AB is a paid consultant to Pfizer in connection with the development of this manuscript. DPJ has received consultancy fees from Alnylam, Blade Therapeutics, GSK, and Pfizer and research grants from Array Biopharma, Eidos, and Pfizer. JWK discovered tafamidis at the Scripps Research Institute; is a shareholder of FoldRx Pharmaceuticals, acquired by Pfizer Inc in October 2010 (the companies that developed tafamidis into a drug); and receives royalty payments from tafamidis patents and sales. JP has received grant/research support from Akcea, Alnylam, Alexion, Eidos, and Pfizer; served as a consultant for Akcea, Alnylam, Cytokinetics, and Pfizer; and served on the speaker's bureau for Akcea and Alnylam. The authors report no other conflicts of interest related to this work.

## Drug Design, Development and Therapy

### Publish your work in this journal

Drug Design, Development and Therapy is an international, peer-reviewed open-access journal that spans the spectrum of drug design and development through to clinical applications. Clinical outcomes, patient safety, and programs for the development and effective, safe, and sustained use of medicines are a feature of the journal, which has also

been accepted for indexing on PubMed Central. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/drug-design-development-and-therapy-journal>
