Abstract: At present, some bacteria have developed significant resistance to almost all available antibiotics. One of the reasons that cannot be ignored is long-term exposure of bacteria to the sub-minimum inhibitory concentration (MIC) of antibiotics. Therefore, it is necessary to develop a targeted antibiotic delivery system to improve drug delivery behavior, in order to delay the generation of bacterial drug resistance. In recent years, with the continuous development of nanotechnology, various types of nanocarriers that respond to the infection microenvironment, targeting specific bacterial targets, and targeting infected cells, and so on, are gradually being used in the delivery of antibacterial agents to increase the concentration of drugs at the site of infection and reduce the side effects of drugs in normal tissues. Here, this article describes in detail the latest research progress on nanocarriers for antimicrobial, and commonly used targeted antimicrobial strategies. The advantages of the combination of nanotechnology and targeting strategies in combating bacterial infections are highlighted in this review, and the upcoming opportunities and remaining challenges in this field are rationally prospected.

Keywords: nanocarriers, antimicrobial, drug delivery, targeting strategies

Introduction

The infection is still considered as one of the most challenging natural threats to which humans are exposed. Broad-spectrum antimicrobials used to be the most common therapy to achieve a certain control on infections. However, increased resistance against antibiotics makes infection difficult to eradicate.

Admitted, abuse of antibiotics is still the primary factor of drug resistance. Apart from this, sub-minimum inhibitory concentration (MIC) is also considered as a non-negligible factor. If bacteria are exposed to the sub-MIC environment for a long time, some bacteria may produce drug-resistant mutations and promote horizontal transfer of antibiotic resistance genes,¹⁻⁵ not only this, low-level antibiotics can significantly induce biofilm formation, making the MIC level rise even more sharply.⁶

However, the MIC level is not as easy to achieve as expected, which mainly occurred in the following three different circumstances. (1) The physiological and drug effects, such as blood flow, vascular permeability, drug physical and chemical properties, and drug affinity to the tissue, could make the distribution of drug to certain infected tissues difficulty. (2) Bacteria phagocytosed by macrophages may

be protected from the host's immune system and survive intracellularly. However, only limited antibiotics could be delivered across the cell membrane, which was under MIC to inhibit the intracellular bacteria. (3) In addition to planktonic cells, bacteria that colonize living surfaces that are altered by certain damage typically form biofilms, in which those bacteria are attached to the substratum or each other and embedded in the extracellular matrix.⁷

In order to achieve or maintain the MIC, nanocarrier with certain strategies has become a research hotspot, which could improve the drug concentration in local targeted sites or inside the cells. This review would summarize different kinds of nanocarriers including several abiotic nanocarriers (liposomes, nanoparticles, conjugate, etc.) and biological biocarriers (adenovirus, lysozyme) to realize targeting strategies that indicates an effective direction for treatment (Figure 1), and focus on three major aspects of targeting strategies: ①targeting bacteria, ②responding to the microenvironment altered by pathogens, ③targeting bacterially infected cells (Table 1). Although most vectors we summarized do not have antibacterial activity, they can also target infection or response environmental change through the modification of ligands or functional groups, so as to achieve local drug release beyond the MIC. At the same time, we also summarized partial antibacterial active carriers, and their combined application with antibiotics is an effective way to solve bacterial resistance.

More importantly, this review systematically summarizes drug-targeted delivery strategies based on bacterial targets and hopes that the carriers are more than just the precise delivery of antibiotic, and has certain universality: that is, a delivery strategy can be applied to a certain class or species of bacteria with the same or similar targets.

Targeting by Microenvironmental Excitation

In view of the fact that certain bacteria colonize the internal environment of the human body, they also change the surrounding microenvironment, which may cause certain inflammatory reactions. Some bacteria can reduce the local pH value of infected tissues through anaerobic fermentation triggered by hypoxia, and host immune response can further reduce the local pH value of bacterial sites through the mechanism of lactic acid production during the process of phagocytosis. In addition, certain bacteria excrete enzymes during growth and reproduction, which is also the key to responsive drug delivery systems. Therefore,

researchers can design targeted, controlled-release intelligent drug delivery systems, which can be used to treat diseases caused by bacterial infection.

Utilizing Changes in pH to Specifically Release Drug

Bacterial growth produces acidic metabolites such as acetic acid, lactic acid and carbon dioxide due to hypoxic conditions, causing decrease in pH and increase in acidity. A kind of drug delivery system that specifically releases at the site of infection can be designed based on this pH change.^{8,9} For instance, surface-charge-converting polymer-based nanoparticles (NPs) are designed to target bacterial cell walls, this vector has no targeting ability at pH 7.4, but strongly adheres to the bacterial surface at acidic pH and subsequently delivers the antimicrobial drug. The poly (D, L-lactic acid-co-glycolic acid)-b-poly (L-histidine)-poly (ethylene glycol) (PLGA-PLH-PEG) NPs undergo surface charge conversion by selective protonation of the imidazole group of PLH at low pH. The NPs do not have the targeting ability at pH=7.4. When acidic, the PLH segment will be positively charged. This charge transfer promotes a strong electrostatic bond between NPs and bacteria due to negatively charged bacterial cell walls.⁹ At the same time, another means is polyelectrolyte multilayer (PEM) coating. PEM coating is composed of cationic antibiotics with tannic acid (TA), for which the films allow the effective retention of antibiotics at pH 7.4. During the growth of bacteria, such as the *Staphylococcus epidermidis* (*S. epidermidis*) or *Escherichia coli* (*E. coli*), which are capable of, respectively, producing lactic acid and acetic acid, pH begins to decrease and the electrostatic interaction between the layers gradually disappears, resulting in the selective release of the antibiotic.^{10,11}

The treatment of *Helicobacter pylori* (*H. pylori*) is an important challenge. The reason is that the bacteria locate in the inner layer of gastric mucus, so that drug delivery needs to overcome highly acidic gastric environment. A novel pH-responsive gold nanoparticle-stabilized liposome was designed. Small chitosan-modified gold NPs are adsorbed onto the outer surface of the negatively charged phospholipid liposomes. The nanoparticle stabilizers were found to cause lipid surface remodeling at the point of adsorption of the NPs, reducing the surface tension of the liposomes and further enhancing the stability of the liposomes. It has been well documented that the pH in the

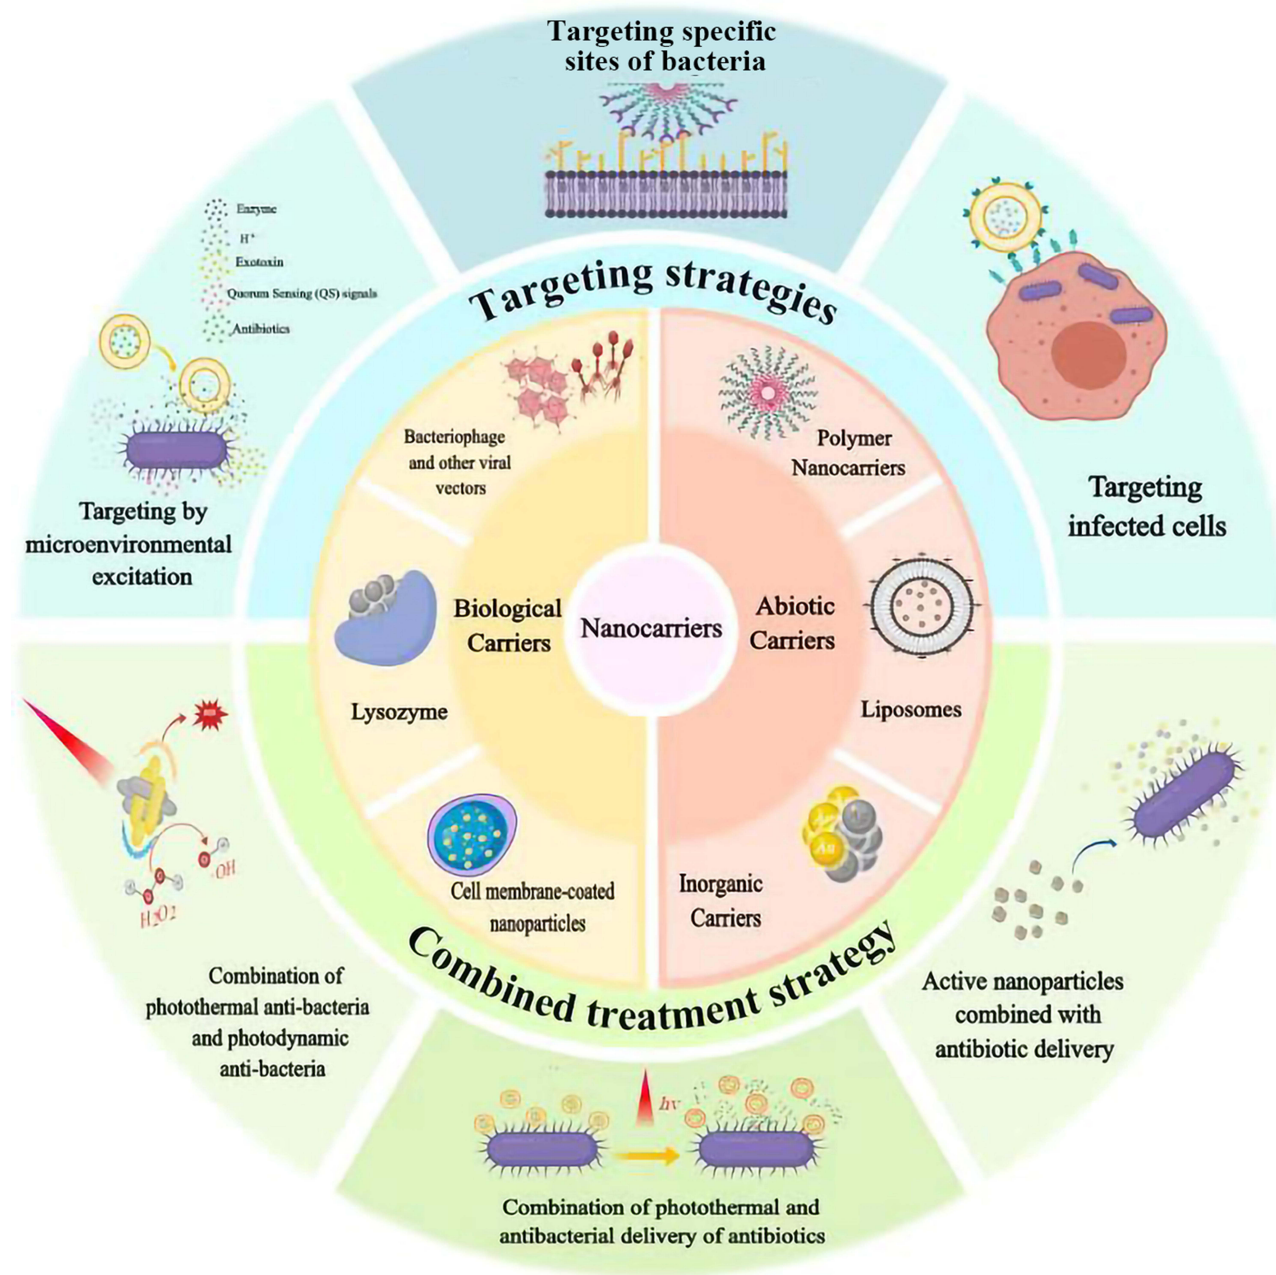

Figure 1 The targeted and combined strategies for antibacterial treatment with application of abiotic and biological nanocarriers.

gastric mucus layer ranges from pH = 1.2 in gastric acid to pH = 6.0 in the gastric mucosa to pH = 7.4 in *H. pylori* colonized epithelial cells.^{12,13} Liposomes are stable at gastric pH, when stable liposomes are present in a near neutral (pH = 7.4) environment, gold stabilizers are separated from the liposomes and freed by reducing the high surface tension of the liposomes. Liposomes can be actively fused with bacterial membranes.¹³

Cysteine-bound chitosan, derivative-thiolated chitosan (Cys-CS), has mucoadhesive and anticoagulant functions.

Cys-CS/PMLA nanoparticles were prepared from positively charged chitosan and negatively charged PMLA. And the zeta potential of these nanoparticles were positive, so they can interact with the negative cell wall of the bacteria. Therefore, the effects of Cys-CS and PMLA can be utilized to prepare multifunctional NPs that specifically target and decompose bacterial membranes. The results showed that amoxicillin-Cys-CS/PMLA NPs have good pH-sensitivity, can prevent the release of amoxicillin in gastric acid, and make the drug adhere to the gastric

Table 1 Summary of the Antibacterial Strategies

Strategies	Targets	Nanovectors	Bacteria
Microenvironmental excitation	Changes in pH	Surface-charge-converting NPs	G ⁺ (<i>S. aureus</i>)
		Polyelectrolyte multilayer film coating	<i>S. epidermidis</i> ; <i>E. coli</i>
		Gold nanoparticle-stabilized liposome	<i>H. pylori</i>

		Vancomycin-terminated AuNPs	Vancomycin-resistant <i>Enterococci</i> ; <i>E. coli</i>
		TiO ₂ -Ag NPs	<i>C. albicans</i> ; <i>A. albicans</i>
		Peptide-like oligomers	G ⁺ (<i>S. aureus</i>)
	Photothermal & photodynamic antibacterial	Au-Ag core-shell NPs	<i>S. aureus</i>
		PDA @ Au-Hap	<i>S. aureus</i> ; <i>E. coli</i>
		PEDOT: ICG @ PEG-GTA NPs	<i>S. aureus</i> ; <i>E. coli</i>
		Fe ₃ O ₄ @ PDA NPs	<i>S. aureus</i> ; <i>E. coli</i>
	Photothermal & delivery of antibiotics	Gold nanocage @ daptomycin @ staphylococcal protein antibodies	<i>S. aureus</i>
		Near infrared activated thermosensitive liposomes	<i>P. aeruginosa</i>

mucosa, increasing the residence time of the stomach for the target. At the site of *H. pylori* infection, the prepared NPs become unstable and disintegrate due to its pH-sensitivity, and then the antibiotics are released locally and act on *H. pylori*.¹²

Using Enzymatic Hydrolysis to Release Drugs

Bacteria can produce enzymes to maintain normal life activities. The invasive enzymes produced by microorganisms are associated with their pathogenicity. Although most of them are intracellular enzymes, and bacteria can also produce extracellular enzymes, such as proteases, amylases, and cellulases. Most of the extracellular enzymes are hydrolases, which can degrade macromolecular substances into small molecular substances to make use of by microorganisms.

Therefore, according to this strategy, a drug delivery system based on an enzyme response carrier can be designed to realize the targeting of infected sites. Since bacteria can secrete amylase, dextrin was designed as a polymer carrier to carry colistin to the site of infection.¹⁴ Therefore, by using Polymer masked-unmasked protein therapy (PUMPT), the polymer binds to the drug to “mask” the protein or peptide, allowing it to hydrolyze at a specific site of infection. As a kind of polymer, dextrin has strong water solubility and is easily degraded by amylase to produce maltose (α -1,4) and isomaltose (α -1,6). At the same time, it can be modified by functional groups (such as succinylation), so as to effectively load antibiotics and “mask” the activity. And the degradation of dextrin by α -amylase allows the local environment to trigger the recovery of drug activity. More importantly, succinylation will change the rate of dextrin degradation, thereby controlling antibiotics release rate. Therefore, succinylated dextrin could combine with colistin to form dextrin-colistin conjugates, which are bound via 3 primary amino groups. Amylases secreted by bacteria will destroy the conjugates’ glycosidic bonds, forming oligosaccharides and/or maltose linked colistin. Exposed cationic amine groups on colistin play an important role in the interaction of colistin with bacterial lipopolysaccharides^{15,16}.

Similarly, besides amylase, phospholipases and lipase can also be used as the keys to stimulate carriers. It is known that *H. pylori* can secrete phospholipid A2 (PLA2).

This enzyme is capable of hydrolyzing membrane phospholipids, causing mucosal damage and facilitating bacterial survival. At the same time, PLA2 can destroy membrane integrity, allowing the payload liposomes to be triggered and release antibiotics. Therefore, it has been studied to synthesize PLA2 responsive liposomes from PLA2-responsive lipids and stabilize them with small chitosan-modified gold NPs. When the stabilized liposomes are located near the *H. pylori* bacteria, the PLA2 secreted by the bacteria will hydrolyze the phospholipid, impair membrane integrity, and release the drug. What is more, the higher the PLA2 concentration, the more the drug will be released.⁴ In addition, the use of a lipase-sensitive polymer triple-layered nanogel (TLN) as drug carriers to accurately carry antibiotics is also being investigated. Its exterior has a hydrophobic poly(ϵ -caprolactone) (PCL) chain to surround the polyphosphate core, preventing the antibiotic from reaching the site of infection from the polyphosphate core. Once the TLN senses lipase-secreting bacteria, the PCL “fence” of the TLN is degraded to release antibiotics.¹⁷

Using Exotoxin to Release Antibiotics

The bacterial exotoxin is mainly a toxic protein produced by gram-positive bacteria in the course of living, which can be secreted into the body or released after the cell is broken. The exotoxin usually consists of two subunits (the toxic unit and the receptor-binding unit). It can be divided into neurotoxins, cytotoxins and enterotoxins, and expresses toxicity in several different ways, such as destroying target membrane integrity, inhibiting target cell protein synthesis, and blocking neurotransmitter release. Typically, the toxin is inserted into the host cell membrane, resulting in the formation of transmembrane pores.^{18,19} At the same time, different bacterial toxins own the same characteristic, that is, the toxin protein undergoes a conformational transition under the induction of acidic pH, exposing the hidden hydrophobic domain. This facilitates the incorporation of the toxin into the cell membrane and translocation into the cytoplasm in whole or in part.²⁰ This conformational transition promoted by acidic pH allows the protein to penetrate into the hydrophobic core of the lipid, helping to form pores. According to this principle, the toxins secreted by the target bacteria can then be utilized and used to trigger the release of the therapeutic payload, thereby killing the bacteria.

Therefore, some researchers have designed a kind of gold nanoparticles stabilized-liposome triggered by

bacterial toxin. The drug is protected by the nanocarriers and will not be released. Only when the bacterial toxin activates the liposome, the drug is selectively released at the site of bacterial infection. The binding of chitosan-modified gold NPs to the surface of the liposomes can effectively prevent the liposomes from merging with each other and slow the release at non-infected parts. When the liposomes are transported to the site of infection, the secreted toxin will be inserted into the liposome membrane and form a pore through which the antibiotic is released, allowing the location to reach a high drug concentration.²¹ Similarly, according to the same principle, some researchers have designed mesoporous silica nanoparticles (MSNs) with bacterial toxins-responsive lipid bilayer surface shells. The lipid material prevents drug release from MSNs and can be degraded by bacterial toxins at the site of infection to rapidly release the drug, thereby achieving effective bacterial inhibition.²²

Targeting Specific Sites of Bacteria

As a complete organism, bacteria have a variety of specific antigens on their cell surface, such as specific proteins, polysaccharides, lipopolysaccharides, teichoic acid and even cell membranes or cell walls. These antigens can be recognized and combined by their ligands, so they provide a good idea for targeted drug delivery.

Targeting Carbohydrates on Bacterial Cell Walls

Lectins can bind to microorganisms containing simple or complex carbohydrates, and the cell wall of *H. pylori* in the stomach has mannose and fucose residues, so the specific lectin can produce strong agglutination with the corresponding mannose and fucose.²³ Therefore, based on this principle, fucose-specific Ulex Europaeus Agglutinin I (UEA I) and mannose-specific Concanavalin A (Con A)-lectins (site-specific) conjugated gliadin nanoparticles (stomach diapause) were designed to deliver drugs in *H. pylori* and binding to its carbohydrate receptor for the treatment of *H. pylori* infection. The gliadin composition contains neutral and lipophilic residues-neutral amino acids can promote interaction with mucous membrane hydrogen bonds, while lipophilic components can interact with biological tissues through hydrophobic interactions, which can enhance adhesion and retention in the gastric mucosa. Gliadin nanoparticles (GNPs) show strong tropism in the upper digestive tract area. These vectors are capable of

targeting and avoiding degradation of the loaded drug. Experiments have shown that UEA I-GNPs and Con A-GNPs have significantly the ability to inhibit bacteria compared to GNPs, and the efficacy is about twice as high.²⁴ At the same time, lectins are also used in many other bacterial infections, and Con A has been found to selectively bind to alpha-mannan and alpha-glucopyranosyl residues in the extracellular polysaccharide matrix of many biofilms.²⁵ Therefore, succinylated Con A (sCon A)-bearing liposomes were designed to deliver triclosan to biofilms of skin-associated bacteria, such as *Staphylococcus epidermidis* and common *Proteus vulgaris* et al.^{25,26}

Targeting Lipopolysaccharide

Among gram-negative bacteria, lipopolysaccharide (LPS), is a unique component consisting of lipid A, core polysaccharide, and polysaccharide O antigen. Among them, the lipid A is a kind of glycolipid compound composed of a pyrophosphate bond by esterified glucosamine disaccharide units, which has a pyrogenic effect and is a toxic component of gram negative (G^-) bacterial endotoxin. LPS is the main component of G^- bacterial endotoxin and determines the diversity of G^- bacterial surface antigenic determinants. Therefore, LPS can be used as a target to design a variety of strategies for the treatment of G^- bacterial infections.

For strategies targeting LPS, a ligand-free targeted DDS is currently available, with molecular imprinting being a newly developed strategy with highly stable drug carriers, which own ligand-like “cavities”. The polymeric carrier can be prepared by inverse microemulsion polymerization, and in this process, the template macromolecule is embedded on the NPs surface and then dialyzed to remove the template molecule to produce a binding site with strong affinity for the target.^{27–30} According to this strategy, molecularly imprinted nanoparticles (MIPNP) using *pseudomonas aeruginosa* (*P. aeruginosa*) amphiphilic LPS as a template for imprinting were designed. Since LPS has amphiphilic properties, it can prepare synthetic spherical NPs by inverse microemulsion polymerization using LPS as a natural template, and the molecular cavity or motif specific to LPS is imprinted on this NP. The ability of NPs with LPS cavities to specifically bind to *P. aeruginosa* was shown by fluorescence polarization and microscale thermophoresis.²⁷

In fact, for the treatment of multidrug-resistant (MDR) bacteria and G^- bacteria that are not sensitive to common

antibiotics, antimicrobial peptides (AMPs) isolated from organisms provide a new therapeutic approach,^{31,32} especially design-specific hybrid peptides that act as a specific targeted AMP (STAMP) to specifically deliver the drug at the site of infection. The focus of this strategy is on the construction of fusion peptides that use a segmental flexible linker to combine the targeting domain with the bactericidal domain; the targeting domain confers selectivity to the killing domain by binding to the pathogen using specific determinants on the surface of the pathogen. In this experiment, LPS was used as a target, various LPS binding peptides were added to design hybrid peptides and analyzed to evaluate the selectivity of hybrid peptides for G^- bacteria and the binding and neutralizing activity of LPS. According to the MIC test, the MIC range of the hybrid peptide was 0.5 to 4 μM , indicating that the hybrid peptides modified by LPS targeting peptide [amino acids 28–34 of lactoferrin (Lf 28–34), amino acids 84–99 of bactericidal/permeability increasing protein (BPI84-99)]-Lf-GUN7 and BPI-GUN7-designed by this strategy showed strong antibacterial activity against both gram-positive and G^- bacteria with little cytotoxicity.³³

Targeting Bacterial Envelope

The bacterial cell envelope is a complex multi-layered structure consisting of the cytoplasmic membrane, cell walls and the outer membrane of G^- bacteria, which are used to protect bacterial microorganisms from adverse environmental effects, trigger immune responses and participate in immune escape. The cell envelope of most bacteria is divided into two main categories. Among them, the cell wall of the gram-negative bacterial peptidoglycan (PG) is thin, and there is an outer membrane containing lipopolysaccharide outside the cell wall. Although the gram-positive bacteria have no outer membrane, they are surrounded by a large number of peptides and have a long anionic polymer-phosphate wall acid. This can be used to design a drug delivery strategy targeting the envelope.^{34,35}

Lysozyme in egg albumin can be utilized to facilitate targeting of phenolic antimicrobial agents. Lysozyme kills sensitive bacteria by degrading the glycoside b-bond between the N-acetylhexosamines of the peptidoglycan layer in the bacterial cell wall. Although lysozyme can be recognized by LPS on the outer membrane of gram-negative bacteria, lysozyme is limited to killing certain gram-positive bacteria.³⁶ Therefore, a strategy for specifically delivering a poorly soluble antimicrobial drug to

a bacterial envelope by using a lysozyme as a carrier to load a drug into the hydrophobic core of lysozyme is derived. The drug-loaded lysozyme is recognized by the LPS or PG on the surface of the bacterial cell and interacts with the bacterial cell envelope to release the antibiotic it carries into the microbial cell.³⁷

Targeting Specific Protein

It has been found that *H. pylori* can specifically express Urea Transport protein (UreI),^{12,13} which can carry urea to the cytoplasmic urease.¹² Chemical urease can hydrolyze urea into ammonia and bicarbonate to neutralize the acidic pH of the stomach environment and form a beneficial environment for *H. pylori*. So, it can be used as a target. Therefore, the urea-modified chitosan derivative ureido-conjugated chitosan (UCCs-2) can be used as a targeting part of the vector combined with UreI of *H. pylori*, so pH-sensitive amoxicillin-loaded AMX-PLGA/UCCs-2 anti-*H. pylori* nanoparticles were constructed. The results show that the NPs have good pH sensitivity, low cytotoxicity, strong specificity and good antibacterial properties. The drug is more efficiently delivered to the site of infection to target eradication of *H. pylori* than non-targeted AMX-PLGA/UCCs anti-*H. pylori* NPs.^{38,39}

Targeting Infected Cells

Intracellular bacteria, especially *Mycobacterium tuberculosis*, *Salmonella*, *Staphylococcus aureus* (*S. aureus*), are important pathogenic microorganisms that pose a serious threat to human health. Killing intracellular bacteria is the key to effective treatment. And macrophages are one of the most susceptible to infection. In some cases, macrophages can protect microbes and even supply important nutrients. Bacteria phagocytosed by macrophages can survive in these cells and protect them from the immune system and antibiotics, which can lead to infection relapse or chronic inflammation.^{40,41}

Most antibiotics have poor permeability to cells and have reduced intracellular activity, so they may be difficult to effectively inhibit intracellular infection. Not only that, many intracellular bacteria are dormant, causing some drug targets to down-regulate, cell membrane permeability to decrease, and reducing the sensitivity of bacteria to antibiotics.⁴² However, some changes in macrophages biological traits may become the key to being targeted by nanocarriers. The nanocarriers could be taken by the

macrophages and release the active ingredients once they are ingested by macrophages.

Arginine Based Nanocarriers for Targeting

In macrophages, *Salmonella* forms a protective membrane called Salmonella containing vacuole (SLV), in which it is able to obtain nutrients from the host for survival and replication. Studies have shown that the bactericidal concentration required to eliminate intracellular bacteria is higher than the bactericidal concentration of extracellular bacteria due to poor permeability of intracellular antibiotics.

It is also known that other intracellular pathogens (*Legionella*, *Brucella*, *Francisella* and *Shigella*) can scavenge several amino acids such as arginine (Arg) from host cells and even cause severe amino acid starvation. Arginine is an important cellular immune response modulator for macrophages, and nitric oxide (NO) is one of the mediators produced by arginine and responsible for the cytotoxic activity of macrophages against intracellular pathogens. There are two pathways for the host to utilize arginine, one that is mediated by nitric oxide synthase to form NO, and the other that is arginase-mediated to form ornithine and urea. Mycobacterial-infected cells showed increased uptake of arginine by cation transporters (CAT1 and CAT2), and more arginine utilization was transferred to the arginase pathway, resulting in decreased production of antimicrobial nitric oxide. *Salmonella* infection also causes upregulation of the CAT1 transporters, resulting in increased arginine uptake, and it was observed that the CAT1 transporters were recruited into SCV. Therefore, due to the increased absorption of arginine by infected macrophages, an arginine-based nanocarrier system (Arg-MSN) was developed, which was used on mesoporous silica nanoparticles (MSN) templates.⁴³

Targeting Mannose Receptors on Macrophages

Recent studies have shown that mannose receptors are present on the surface of macrophages, and based on this, mannosylated liposomes are designed to selectively enhance the uptake of chemistry drugs (ciprofloxacin) or certain natural medicines (andrographolide) by macrophages in vivo after administration.^{44–46} In another study, mannose-anchored solid lipid nanoparticles were designed to selectively deliver anti-tuberculosis drugs (rifabutin) to alveolar

macrophages. In vitro cell uptake showed a six-fold increase in alveolar macrophage internalization by mannose binding. After 24 hours of dosing, free rifabutin was mainly distributed in the kidneys at the early stage and finally distributed in the lungs and liver, while mannose-anchored rifabutin nanoparticles were mostly distributed in the lungs.⁴⁷ Although the uptake of mannosylated liposomes by alveolar macrophages (AMs) was significantly increased, at the same time free mannose significantly inhibited the uptake of mannosylated liposomes, suggesting that the uptake mechanism of AMs on mannosylated liposomes is mannose receptor-mediated endocytosis.⁴⁸ Since the availability of mannose receptors is a factor in the efficient uptake of mannosylated liposomes, it is necessary to determine the optimal ratio of mannosylation that can be used to provide effective macrophage targeting.^{48,49}

The mannose receptor is expressed in AMs, and the surfactant protein (SP) in the epithelial lining fluid (ELF) upregulates the activity of the mannose receptor of AMs. Studies have shown that uptake of mannosylated liposomes by phagocytic cells is accelerated by conditioning based on complement activation. Since SP-A and SP-D have similar ultra-structures to mannose-binding proteins, SP-A and SP-D have high affinity for mannose. While SP-A and SP-D can bind to the mannose receptor and SP receptor of AMs, the uptake of mannosylated liposomes by mannose receptors and SP receptors is increased.⁴⁸

Another application is a mannosylated nanogel drug carrier, and this nanocarrier can undergo degradation by bacterial enzymes to release the drug. The nanogel of the polyphosphate crosslinked core and the PEGylated shell modified with the mannosyl ligand can be degraded by bacterially produced active phosphatase or phospholipase (Figure 2A).⁴¹ Mannosylated nanogels can target antibiotics for macrophages: macrophages express high levels of mannose receptors for uptake of mannosylated nanogels (Figure 2B) and macrophage transport into bacterial infection sites to increase drug accumulation. At the site of infection, macrophages further ingest bacteria, and the degradation of the polyphosphate core containing drugs is initiated by active phosphatase or phospholipase produced by the bacteria. Thus, the nanogel provides macrophage targeting and activatable drug release properties.¹ Nanogels are internalized in endosomes or early lysosomes and are in tight vicinity to bacteria in phagosomes or phagolysosomes. Since the above vacuoles can be incorporated into macrophages, the nanogel can be triggered by microbial enzymes and endolysosomal enzymes to release the drug.⁴¹ Nanogels

Figure 2 (A) Schematic illustration of a vancomycin-loaded mannosylated nanogels (MNG-V) can be degraded by bacteria secreting phosphatase or phospholipase. (B) Schematic illustration of targeted uptake of MNG-V, transport, degradation, drug release and bacteria inhibition.

loaded with vancomycin have an effect on methicillin-resistant *S. aureus* (MRSA) and release drugs sufficiently to inhibit bacterial growth.¹

Enhance Macrophage Uptake with Novel Liposomes

When conventional liposomes are intravenously injected, they are easily recognized by cells of the mononuclear phagocytic system (MPS), especially in the liver and spleen. Therefore, the targeted delivery of drugs to organs other than the liver and spleen and the role of conventional liposomes is limited.⁵⁰

Sterically stabilized liposomes (SSLs) were then designed as drug delivery tools for mycobacterial infections. Unlike conventional liposomes, hydrophilic poly(ethylene) glycol (PEG) coating on the surface of the liposome can provide steric hindrance around the liposome, thereby reducing MPS rapid identification and uptake of cells.^{50,51} Therefore, SSLs could circulate blood for a relatively long period of time, creating the possibility of targeting infected tissues outside the liver and spleen. After long-term circulation in the blood, SSLs ooze out in infected tissues and eventually enter deep tissue macrophages, and SSLs can serve as a site-specific drug delivery system in *mycobacterial* infections.

Transfection of Macrophages with Viruses for Specific Antibacterial Peptides

Antimicrobial peptides exhibit potent antibacterial activity against a broad spectrum of pathogens, including intracellular bacteria, exhibiting strong lytic activity against both gram-positive and gram-negative bacteria, but are less cytotoxic to other cells in the human body. Therefore, a gene delivery system can be sought that enables cells to express antimicrobial peptides against antimicrobial infections. Compared to other gene transfer methods (retrovirus and cationic lipid), adenovirus does not depend on the state of cell division. In fact, normal macrophages can be efficiently transfected with viral and nonviral expression systems, and experiments have shown that adenoviruses can efficiently transfect macrophages. The adenovirus can then be recombined and can encode the hybrid antimicrobial peptide CAMA-syn encoding gene and the macrophage-specific promoter (MSP) into the adenovirus. The recombinant adenovirus-mediated antibacterial peptide CAMA-syn is expressed in macrophage and expresses the MSP promoter, showing macrophage antibacterial activity and macrophage specificity. It has been experimentally shown that CAMA-syn produced by an adenoviral vector can significantly increase the

antibacterial activity against gram-positive and gram-negative bacterial strains.⁵²

Combined Treatment Strategy

Nanomaterials are expected to enhance the therapeutic effect of bacterial infection because of their unique physical and chemical properties.⁵³ Nanomaterials can not only kill bacteria alone but also perform a variety of germicidal pathways, making it difficult for bacteria to adapt to these treatments. These pathways depend on the shape and size of the core materials inherent in the nanomaterials and the modification groups and loaded antibacterial substances. Antimicrobial agents based on nanomedicine have proved the effectiveness of their bacterial infection.⁵⁴ In this chapter, we mainly focus on the strategy of interaction between nanomedical materials and bacterial cells, which plays a key role in improving the therapeutic effect.⁵⁵ According to the role of nanomaterials in antibacterial therapy, a new treatment strategy for bacterial infection was developed.

Active Nanovectors Combined with Antibiotic Delivery

Simultaneous delivery of active antibacterial nanoparticles and antibiotics is a promising combined antibacterial method. Stearylamine (SA) is a compound that can be used to target biofilm bacteria.^{56,57} Since the liposome of the cation-containing SA differs from the surface charge of the bacterial membrane or the negatively charged biofilm matrix compound, the liposome is bound to the bacterial cell membrane by electrostatic force. Experiments have demonstrated the attraction interaction between cationic liposomes mediated by electrostatic effects and negative potential points on the surface of bacteria or in extracellular mucus.^{25,26} Liposomes composed of phosphatidylinositol (PI) and a small amount of dipalmitoylphosphatidylglycerol (DPPG) can also adsorb into biofilms formed by bacteria in the skin and oral cavity. The hydroxyl content of the inositol and glycerol heads in lipids plays an important role, and hydrogen bonds with teichoic acid may be formed in the sugar saccharides of the bacteria, allowing the liposomes to tightly bind to the bacterial biofilm and release antibiotics.^{25,58}

Not only liposomes, NPs can also be an effective choice for active carriers. Gu and his colleagues used this strategy to design mesoporous silica nanoparticles loaded with silver and levofloxacin (Ag@MSNs@LEVO) (Figure 3).⁵⁹ The

researchers prepared silver-coated mesoporous silica nanoparticles and then wrapped levofloxacin in the mesopores. The release of Ag⁺ ions permeates the outer membrane of bacteria, making them more vulnerable to levofloxacin released at the same time. Drug-loaded nanoparticles showed synergistic effects on multidrug-resistant *E. coli* in vivo and in vitro. The antimicrobial activity of vancomycin-terminated AuNPs (Au@VanNPs) against vancomycin-resistant *enterococci* (VRE) and *E. coli* was 64 times higher than that of vancomycin itself, and ciprofloxacin-coated gold nanoparticles also had stronger anti-VRE activity.⁶⁰ Different types of metals can be added to the same nanoparticles, so resistance to these nanoparticles will require the target microorganism to undergo several simultaneous mutations to become resistant to several metals. Nanoparticles containing both TiO₂ and Ag (TiO₂-Ag nanoparticles) were found to be more effective against *Candida albicans* and *Aspergillus albicans* than individual Ag nanoparticles and fluconazole.⁶¹

With the development of materials science, there are still some antibacterial active materials become the research hotspot, such as antibacterial peptide-like oligomers.⁶² It can destroy the bacterial cell membrane, is not easy to produce drug resistance, and overcome the shortcomings of AMP being easily degraded by proteases in the body.⁶³ The synergy of new materials and antibiotics can be used as one of the important antibacterial strategies.

Combined Treatment Strategy of Photothermal Antibacterial and Photodynamic Antibacterial

Photothermal antimicrobial activities, such as pasteurization, have been used as a physical antibacterial activity since before penicillin was discovered. It is believed that ordinary bacteria will be sterilized at temperatures above 55°C due to the denaturation of heat shock proteins.⁶⁴ Therefore, people are expected to explore new methods of medical heat generation with high biocompatibility and high efficiency. In recent years, the photothermal effect of near-infrared light has been reported to have a high photothermal conversion efficiency. A series of photothermal nanomaterials have been developed to show strong light absorption ability to near-infrared light and convert light energy into thermal energy. The heat generated can inhibit the development of drug-resistant bacteria and prevent the formation of biofilm structure.⁶⁵ Therefore, photothermal therapy (PTT) is considered to be a safe and effective strategy for the treatment of bacterial infections. Photothermal effect can also be

Figure 3 Schematic illustration of the fabrication of Ag@MSNs@LEVO nanoplateform and its application for a synergistic therapy of drug-resistant infections in vitro and in vivo. The silver core is the supplier of silver source, and the shell of mesoporous silica acts as the drug storage and release channel, which endows the single particle nano-platform with the ability to release antibiotics and silver tower simultaneously.

combined with one or two other strategies to produce synergistic effect of antibacterial activity with better specificity and higher efficiency.⁶⁶

Ding et al⁶⁷ realized two-photon imaging, thermal generation, Ag⁺ release and ROS production of bacteria using positively charged Au-Ag core-shell nanoparticles. *S. aureus* and Au@Ag nanoparticles were incubated for 4 minutes, and 92% of the bacteria were killed under the irradiation of near-infrared laser (820nm). Another interesting example is the hybrid system of gold nanoparticles prepared by Xu et al (Figure 4) and polydopamine-assisted hydroxyapatite (PDA@Au-Hap).⁶⁸ The authors point out that this nanomaterial can catalyze the formation of hydroxyl radicals (OH) from low concentration H₂O₂ so as to improve the photothermal antibacterial properties of 45°C and avoid unnecessary damage to normal tissue. In addition to sterilization, it can also promote the formation of granulation tissue and the synthesis of collagen, and accelerate wound healing. Some conjugated polymers are used to prepare antibacterial nanomaterials with photothermal effect. Two typical examples are Polyaniline (PANI) and poly (3pyr4-ethylenedioxythiophene) (PEDOT). Li et al coated indocyanine green (ICG) on PEDOT nanoparticles by electrostatic attraction, and further coupled it with PEG and glutaraldehyde (GTA) to obtain bacterial targeting.⁶⁹

A special feature of these PEDOT: ICG@PEG-GTA nanoparticles is that ICG can produce reactive oxygen species in near infrared region I (808nm), while PEDOT shows strong absorption in near infrared region II (1064nm), thus forming dual-mode PDT/PTT. They have high photothermal conversion efficiency (71.1%), excellent photostability, low toxicity and good germicidal efficacy (99%).

Dopamine (PDA) has also attracted wide attention recently because it can modify the surface of various materials. It has also been proved to be a photothermal conversion agent.⁷⁰ Fe₃O₄@PDA nanoparticles were synthesized by Liu et al loaded with heat shock protein 70 (HSP70) inhibitor 2-phenylethyl sulfonamide (PES), to form a new type of synergistic antibacterial application nano-platform. Under the irradiation of near-infrared laser, PES can be released from PDA@Fe₃O₄+PES nanoparticles, and specifically interfere with the HSP70, on the surface of bacteria to reduce the tolerance of bacteria to thermal damage, so as to improve the germicidal efficacy.⁷¹ Yu et al also used Fe₃O₄@PDA nanoparticles.⁷² As the core of the third generation dendritic poly (amide-amine) (PAMAM-G3) grafted, the prepared Fe₃O₄@PDA@PMAA@PAMAM nanoparticles showed controllable NO release under near-infrared laser irradiation. The synergistic effect of light and heat

Figure 4 Schematic illustration of photothermal therapy combined with catalysis to achieve antibacterial effects and promote wound healing in vivo. PDA@Au-HAP catalyze the formation of OH from H_2O_2 at low concentration, enhanced photothermal antibacterial performance at 45°C via destruct cell membranes, proteins and DNA, PDA and the release of Ca^{2+} and PO_4^{3-} promote the expression of related genes in NIH3T3 cells, facilitate the formation of granulation tissue and collagen synthesis to accelerate wound healing.

had no bacteriostatic effect on *E. coli* and *S. aureus*, but the bacterial activity and biofilm biomass decreased significantly.⁶⁵

Combination of Photothermal and Antibacterial Delivery of Antibiotics

Meeker et al (Figure 5) constructed a gold nanocage and modified it with daptomycin and staphylococcal protein antibodies.⁷³ These nano-cages can be specifically anchored on the surface of *S. aureus* and produce high temperatures under near-infrared radiation. When heated, daptomycin is released, creating a synergistic chemical-photothermal effect to kill *S. aureus*. After the initial near-infrared irradiation, the germicidal effect was still significant after being placed in the dark for 24 hours. Thermosensitive liposomes have antibacterial activity by synergistic chemical-photothermal therapy.^{74,75} We designed and prepared near-infrared activated thermosensitive liposomes with the ability of photothermal and antibiotic synergistic therapy to eliminate *P. aeruginosa* biofilm. Positively charged and small liposomes help to enter the biofilm microchannel and release antibiotics locally at the infection site. Liposomes can

remain stable at 37°C and release about 80% antibiotics at 45°C. The biofilm dispersion rate is as high as 80%, an increase of 7 to 8 times compared with excessive antibiotics alone, indicating that local antibiotic release and photothermal combination therapy have improved antibacterial efficiency. Drug-loaded liposomes show outstanding therapeutic effect in the treatment of abscess caused by *P. aeruginosa*. This chemical-photothermal therapy can effectively ablate bacteria with low doses of antibiotics.

Conclusions and Outlook

Bacterial resistance caused by the widespread use of antibiotics has set the application of antibiotics in antimicrobial infections in a dilemma. New strategies are urgently needed to improve the pharmacokinetic and nanocarrier-enriched antibiotics at the infection site by means of different drug delivery strategies, which not only improves the antibacterial effect of antibiotics but also helps to reduce the possibility of bacterial drug resistance. This review introduces three targeting strategies based on the pathological characteristics of the bacterial infection site and some combined treatment strategies.

Figure 5 Schematic illustration of the working mechanism of the targeted photoactivatable nano-construct for synergistic photothermal and antibiotic treatment of *S. aureus*.

The application of conventional antibiotics is in a dilemma, such as poor efficacy against drug-resistant bacteria, low therapeutic index, high cytotoxicity and side effects. Fortunately, these drawbacks can be compensated to some extent using various antimicrobial drug delivery system involving nanotechnology. Nanocarriers have small size, high surface-to-volume ratio and are amenable to surface modification, which can bind the receptor or respond to environmental stimuli. So, antibiotics could be accurately released to the site of infection, thereby increasing drug concentration and reducing the side effects of antibiotics in non-infected tissues. Targeted drug delivery using nanocarriers can not only achieve better antibacterial effects by using decreased drug dose but also inhibit the generation of bacterial resistance.

The future development of nano-antibacterial strategies may still focus on the multiple combined treatment, especially the combination of the nanovectors with antibacterial activities (such as cationic liposomes, metal nanoparticles, dendrimers and graphene, et al) and antibiotics or antimicrobial peptide (AMP), making the nano drug delivery system more intelligent and have better application prospects. Since these carriers have certain antibacterial capacities, such as production of ROS, the combination of the two may have synergistic antibacterial effects on the basis of ensuring accurate drug delivery.

In addition, biological vectors (such as viral, lysozymes, biomimetic vectors, et al) also offer many significant advantages compared with abiotic vectors. Viral vectors, especially phages, can autonomously target bacteria by virtue of their own specific proteins. And lysozyme, since it is an antimicrobial enzyme, has effective bactericidal activity against most pathogens. In addition, biological vectors have high transfection efficiency, and thus serve as an ideal vehicle for large molecules, such as genes and polypeptides. These advantages make the biological carriers more worthy of further study.

Although antibacterial carriers have entered the era of nanotechnology, these targeted drug delivery systems still face many challenges, such as carrier stability, safety, and biocompatibility. In the future, with the further research of DDS theory targeted drug delivery system will be gradually improved and be more widely used in antimicrobial therapy.

International Journal of Nanomedicine

Dovepress

Publish your work in this journal

The International Journal of Nanomedicine is an international, peer-reviewed journal focusing on the application of nanotechnology in diagnostics, therapeutics, and drug delivery systems throughout the biomedical field. This journal is indexed on PubMed Central, MedLine, CAS, SciSearch®, Current Contents®/Clinical Medicine,

Journal Citation Reports/Science Edition, EMBase, Scopus and the Elsevier Bibliographic databases. The manuscript management system is completely online and includes a very quick and fair peer-review system, which is all easy to use. Visit <http://www.dovepress.com/testimonials.php> to read real quotes from published authors.

Submit your manuscript here: <https://www.dovepress.com/international-journal-of-nanomedicine-journal>
